CONTENTS FOR OCTOBER, 1940

Silver Anniversary Number

We Celebrate Our Silver Anniversary. Warren T. Vaughan, M.D., Richmond, Va.	1
The Autonomic Nervous System Considered in Relation to Experimental and Clinical Phenomena. Dennis E. Jackson, Ph.D., M.D., Cincinnati, Ohio	4
Interaction of Vitamins and Drugs With Cell Catalysts. Frederick Bernheim, Ph.D., Durham, N. C.	20
Coenzymes I and II in Human Blood. S. P. Alber, Ph.D., M. B. Koch, D.A., and T. D. Spies, M.D., Cincinnati, Ohio	31
Clinical Laboratory Determination of Vitamin Nutriton. Henry Field, Jr., M.D., and Daniel Melnick, Ph.D., Ann Arbor, Mich.	45
The Role of Blood Chilling Anomulies in the Hemorrhagic Diseases. John H. Ferguson, M.D., Ann Arbor, Mich.	52
Hemolytic Anemia. Russell L. Haden, M.D., Cleveland, Ohio.	65
Preserved Blood "Dunks" in Relation to Transfusion in the Treatment of Disease. John A. Kolmer, M.D., Philadelphia, Pa.	82
The Reticulo-Endothelial System: Its Physiology and Pathology. Charles A. Donn, M.D., F.A.C.P., Columbus, Ohio.	89
The Mechanism of Bacterial Allergy. J. Brimfenbrenner, Ph.D., St. Louis, Mo.	102
Treatment of Allergic Disorders With Diamine and Diaminase. R. L. Alexander, M.D., St. Louis, Mo.	110
Capillary Factors in Processes of Disease. Virgil H. Mann, M.D., Philadelphia, Pa.	117
Possible Significance of the Inhibitory Effect of Fever on Anaphylactic Phenomena. Paul de Krull, Ph.D., Holland, Mich., and Walter M. Simpson, M.D., Dayton, Ohio.	125
Development of New Organic Chemicals for Therapeutic Use. F. P. Birke, Ph.D., Ann Arbor, Mich.	131
The Serology of Syphilis. Heinen L. Kuhn, Sc.D., Ann Arbor, Mich.	139
The Takata-Ara Test in Liver Disease. Thomas Byrd Naguib, Ph.D., M.D., Rochester, Minn.	156
A Discussion of Electrophoresis With Special Reference to Serum and Allergens. H. A. Abramson, M.D., and D. H. Moore, Ph.D., New York, N. Y.	171
Recent Procedures Applicable to Problems in Lipid Metabolism. H. C. Eckstein, M.S., Ph.D., Ann Arbor, Mich.	181
Clinical Studies of the Organic Acid-Soluble Phosphorus of Red Blood Cells in Different Acidotic States. George M. Guest, M.D., and S. Harnpuri, M.D., Ph.D., Cincinnati, Ohio.	190
Some Chemical Observations on the Human Heart in Health and Disease. Victor G. Myers, Ph.D., D.Sc., and George H. Mangun, Ph.D., Cleveland, Ohio.	199
Kidney Parenchyma, Circulating Blood Plasma, and Tissue Fluids in Diuretics. George Herrmann, M.D., Galveston, Texas.	211
The Functions of the Carotid and Aortic Bodies. Carl F. Schmidt, M.D., Philadelphia, Pa.	223

TABLE OF CONTENTS ON INSIDE COVER

CONTENTS FOR NOVEMBER, 1940

Progress

- Tuberculosis—Present and Future. Gerald B. Webb, M.D., Colorado Springs, Colo. 287

Clinical and Experimental

- Dissecting Aneurysm of the Aorta. Abel Leshit, M.D., F.A.C.P., Dexter S. Levy, B.A., M.D., and James R. L. Cole, M.D., Buffalo, N. Y. 290
- A Note on *Saccharomyces fragilis* Jørgensen Associated With Pathologic Conditions in Human Itelugs. Norman Colander Laffer, Ph.D., Tucson, Ariz. 294
- The Action of Epinephrine Injected Into the Peritoneal Sac. Philip Mikkensdorfer, Ph.D., and J. A. Bone, M.S., M.D., Chicago, Ill. 297
- Torula Infection of the Central Nervous System. Leon H. Balldberg, M.D., Nyack, N. Y. 299
- Cutaneous Hypersensitivity to Iodine. John L. Jacobs, M.D., and Abraham Colmes, M.D., Boston, Mass. 302
- Acute Endocarditis Due to an Anaerobic Pneumococcus. Alvin Hallander, M.S., and Eva Landberg, M.D., Brooklyn, N. Y. 307
- A Qualitative and Quantitative Study of Atmospheric Pollen at Moscow, Idaho. Jean R. Daubendire, M.S., Moscow, Idaho 311
- Intramuscular Administration of Sodium Sulfapyridine. Lynn T. Hall, M.D., Edward Thompson, M.D., and Raymond J. Wyrens, M.D., Omaha, Neb. 314
- Giant Cell Tumor of the Frontal Bone. J. Roy Keegan, M.D., and Charles P. Baker, M.D., Omaha, Neb. 319

Clinical Chemistry

- A Theory of Porphyrinogenesis. W. J. Turner, B.S., M.D., North Little Rock, Ark. 323
- Studies on the Intravenous Injection of Colloids. II. Effects of Gum Arabic on Certain Functions of the Liver With a Note on Its Effects on the Production of Immune Bodies. W. Knowlton Hall, Ph.D., New Orleans, La., and R. H. Gibson, Ph.D., and L. A. Weed, M.D., Ph.D., Iowa City, Iowa 330
- Blood Serum Magnesium in Bronchial Asthma and Its Treatment by the Administration of Magnesium Sulfate. Victor G. Henry, M.D., Philadelphia, Pa. 340
- Sodium and Potassium Studies in Persons With and Without Arterial Hypertension. Dudley W. Bennett, M.D., San Francisco, Calif. 344
- The Effect of Iron on Phosphorus, Calcium, and Nitrogen Metabolism. Adelaide P. Harer, Ph.D., and Willis M. Fowler, M.D., Iowa City, Iowa 351
- Alteration of Glucose Tolerance in Patients With Disease of Pituitary, Thyroid, and Adrenal Glands by Changes of Diet. James A. Greene, M.D., and L. W. Swanson, M.D., Iowa City, Iowa 360
- The Comparative Iodine Content of Whole Blood and Serum. Karl F. Klassen, M.D., Ruth L. Merbaum, S.M., and George M. Carls, Ph.D., M.D., Columbus, Ohio 363
- Comparative Studies on the Absorption of Sulfanilamide. Walter J. Siebert, M.D., and Frederick Loose, St. Louis, Mo. 371

Laboratory Methods

General

- Simultaneous Arterial and Venous Blood Cultures. Maynard Murray, M.D., and Frank Moosatch, R.S., Cincinnati, Ohio 382
- A Simplified Apparatus for Constant Rate Injections. Alfred E. Koehler, M.S., Ph.D., M.D., Santa Barbara, Calif. 383

(Contents continued on page 3.)

Useful Therapy in Addison's Disease with **PERCORTEN***

DESOXYCORTICOSTERONE isolated¹ as one of the principles of the adrenal cortex, is synthetically prepared and supplied by Ciba in the form of the acetic acid ester, known as PERCORTEN. Percorten is indicated in Addison's disease as shown by various investigators.

In a detailed study on 8 patients, Thorn and associates² describing the effects on body weight, blood pressure, plasma volume, sodium-potassium-chloride balance demonstrate the improvement which can be obtained. From these studies it also appeared that 1 mg. of desoxycorticosterone acetate was equivalent to about 3 cc. of adrenal cortical extract injected subcutaneously in divided doses.

Other conditions in which insufficiency of the adrenal secretion has been assumed, such as are associated with surgical procedures involving the adrenal gland, post-infectious asthenia, acute infections, surgical shock, etc., have been experimentally treated with Percorten and encouraging results have been reported.

Forms of Issue — Ampules of 5 mgm. in 1 cc. sesame oil — boxes of 3 and 6. Vials, rubbercapped: 10 cc., each cc. contains 5 mgm. in sesame oil.

1. Reichstein and Euw—*Helv. Chim. Acta* 21:1197, 1938.
2. Thorn, et al—*Am. Jl. Med. Sciences* 197:718, 1939; *Jl. Clin. Invest.* 18:449, 1939.

CIBA PHARMACEUTICAL PRODUCTS, Inc.
SUMMIT, NEW JERSEY

*Trade Mark Reg. U.S. Pat. Off. Word "Percorten" identifies the product as desoxycorticosterone acetate of Ciba's manufacture.

Shows stack of Adams Slide Trays, each holding 50—3"x1" slides. Note easy identification and accessibility of slides. The tongue and groove arrangement permits stacking of trays—removal of each tray as required.

Adams SLIDE TRAYS

(Microtechnic System)

Simplifies Handling and Safe Storage of Microscope Slides

Adams Slide Trays facilitate orderly arrangement and classification of microscope slides. The cabinet and movable Rolling Stand simplify the handling and safe storage of the slides. The finely made trays will resist the action of usual laboratory solvents. They will not warp, even when placed in the oven during conditioning of slides.

Units are available as follows:

- Slide trays, each holding 50—3"x1", 35—3" x 1½", or 25—3" x 2".
1 doz. 3 doz. 6 doz.
\$12.50 doz. \$11.25 doz. \$10.00 doz.
- Tray Cabinet, holding 25 trays... \$35.00 ea.
- Rolling Cabinet Stand, for transporting cabinet \$12.00 ea.
- Complete—Cabinet, Rolling Stand and 25 trays \$65.00 ea.

Your order will receive our careful attention. Descriptive circular No. 229 JL sent on request.

Cenco-Sheard-Sanford

“PHOTELOMETER”

*More Accurate—More Rapid—More Reliable
Than a Colorimeter*

PHOTELOMETRIC methods of analysis replace many of the usual colorimetric methods with slight modifications in procedure. No comparison standards are needed. A single calibration for any particular unknown holds indefinitely. Such simplification in laboratory practice greatly facilitates the work and saves much time in important analyses. In the hospital and clinical laboratory, photelometric methods are being used for the determination of hemoglobin, sugar, creatinine, bilirubin, magnesium, non-protein nitrogen, urea nitrogen, uric acid, potassium, and cholesterol in blood and for the rose bengal test of liver function.

Size A widely used for water analysis; B for general culture work; C for Wassermann tubes.

Aloe-Willett Culture Tube Caps

- Eliminate Cotton Plugs
- Economical in Time and Money

Aluminum caps, especially made for the purpose, supplant cotton plugs in tube cultures, with a resulting economy of time and materials. They can be used repeatedly. Being made of 1/32" aluminum they will not easily become bent. In use, culture tubes containing media are racked up with the caps in place and autoclaved. The tubes are then used before noticeable evaporation takes place. To our knowledge no contamination difficulties have ever been experienced in using these caps.

JL24-152—Aloe-Willett Culture Tube Caps:

For Tubes Size mm.	Depth mm.	Width mm.	Per Dozen
Size A 25 x 200	28	30	\$0.65
Size B 18 x 150	25	20	.60
Size C 13 x 100	25	15	.55

"A Product of Corning Research"

THE Corning Glass Works representative who calls on you is a trained technician. He speaks your language. He understands your problems.

He comes to give and to receive. To give you news of recent developments in the laboratory field—new methods, new discoveries, new products. To obtain from you your experiences with various laboratory ware. To get your opinion of recent improvements and to learn, first-hand, how we in Corning can make our ware ever better.

All this might be called Field Research. For from these first-hand experiences of our field men has come the inspiration for much of our Research in Glass. From you, from our distributors and from their representatives have come ideas, suggestions, needs—yes, and criticisms—that have constantly improved laboratory glassware and made laboratory technique better, more accurate, faster, safer and less expensive.

The card of a Corning field contact man is the card of cooperation. He comes in the spirit of mutual helpfulness—to you and to the field of Science as a whole. He, too, has a part in Corning Research.

The Aloe Precision Calvarium Clamp

A simplified and improved American-made Calvarium Clamp, designed to meet the requirements of hard routine use. It consists of a bow of hardened steel, chromium plated, provided with tooled steel screw pins at each end as well as an adjustable holding pin at the top. The handle is constructed with an elongated grip of monel metal to prevent slipping while in use. Dimensions: distance between bows, $7\frac{3}{4}$ inches; distance between lateral screws when fully closed, 4 inches; height overall, $10\frac{1}{2}$ inches.

PRICE—No. L11-185—Aloe Precision Calvarium Clamp\$22.50

New Third Edition Now Ready!

APPROVED LABORATORY TECHNIC

Clinical, Pathological, Bacteriological, Mycological
Parasitological, Serological, Biochemical, and Histological

By JOHN A. KOLMER, M.D., F.A.C.P.
and FRED BOERNER, V.M.D.

These up-to-the-minute new laboratory methods — presented in full detail in the 3rd edition — are visible proof that this text is the last word on the matter of laboratory technic:

Quick's method for the quantitative determination of prothrombin.

Method for the examination of semen.

Sparkman's method to determine urobilinogen in the urine and feces; as a test for liver function.

Method for the determination of serum lipase in relation to disease of the pancreas.

The technic of the simplified Kolmer complement fixation test.

Eagle modification of the Wassermann test.

Methods for the determination of vitamin C in urine and plasma — now so frequently required.

Methods for the determination of sulfanilamide and other sulfonamide compounds in the blood and urine.

And there are more — equally essential! Tried and proven in the past, this text is now even more indispensable. Put it on your shelves and bring to your laboratory work the best guide available. Don't fail to see the new third edition!

952 pages. 382 illustrations in
the text, 12 in color.

Sharpen Microtome Knives

at low cost, with improved results!

with the ALOE PRECISION Microtome Knife Sharpener

Developed by a manufacturer of fine microtome knives, and used commercially for reshaping, this machine has been thoroughly tested by long use. The apparatus consists of a special honing wheel operated by a motor. The desired bevel is always obtainable by use of knife backs of differing diameter, the back and knife edge being held evenly against the wheel during sharpening. Knives may be sharpened with the Aloe Precision Sharpener a hundred or more times before re-grinding becomes necessary. A few strokes on the linen strop provided smooths off the burr, leaving a perfect edge.

JL19-462—Aloe Precision Electric Microtome Knife Sharpener, for 110 V., A. C., complete with strop\$87.50

Above, the sharpener. The wheel sits at a slight angle, permitting ease in holding knives on either side. Below, the linen strop.

Announcing THE MERCK MANUAL OF THERAPEUTICS AND MATERIA MEDICA

• SEVENTH EDITION—1940 •

The Merck Manual is intended only for physicians, dentists, pharmacists, chemists, nurses, and those in allied professions.

1462 pages clearly printed on fine paper, bound in blue Fabrikoid covers with gold stamping.

PRICE \$2.00
OUTSIDE U. S. A. \$2.50

The seventh edition of THE MERCK MANUAL OF THERAPEUTICS AND MATERIA MEDICA, completely revised, is now available. The progressive period which has elapsed since the publication of the sixth edition of this widely-acclaimed book necessitated revolutionary changes and additions of text.

• **FROM AUTHORITATIVE SOURCES**—The section on Therapeutic Indications, 256 chapters of useful and authoritative information, includes in the prescriptions, the nomenclature of the eleventh edition of *The United States Pharmacopoeia* and the sixth edition of *The National Formulary*. The discussion in each chapter has had the benefit of expert scrutiny of outstanding specialists with hospital and teaching affiliations in their respective fields. As in the case of the preceding edition, the therapy was outlined by the late Dr. Bernard Fantus, Professor of Therapeutics, College of Medicine, University of Illinois.

• **NEW FEATURES**—Of the same convenient pocket-size as the sixth edition, there is included a comprehensive index for quick reference to the chapters on etiology, diagnosis, therapy, prophylaxis, and general regimen. Among the new chapters are those on Bile Tract Disease, Circulatory Failure, Granuloma Inguinale, Granulocytopenia, Impotence, Hypoglycemia, Hypo-ovarianism, Obesity, Roentgen-Ray Sickness, Lymphadenopathies, Jaundice, Spirochetal Jaundice, Psychoneuroses, and Psychoses.

• **PUBLIC HEALTH**—The chapters on subjects of special interest to public health, such as Syphilis, Malaria, Amebiasis, Typhus Fever, Yellow Fever, Dengue, Pellagra, Tularemia, Brucellosis and others, have had the special benefit of outstanding cooperation from experts whose duties pertain to those diseases.

• **A TRADITIONAL SERVICE**—Again presenting its traditionally recognized service, the seventh edition of THE MERCK MANUAL eclipses its predecessor in every respect. Orders, at a nonprofit price of \$2.00 per copy, will be filled in the order of their receipt.

This coupon will bring The Merck Manual promptly. Mail it today.

The SOMOGYI
URINE SUGAR
COMPARATOR

For the rapid
estimation of
urine sugar

This comparator has been prepared for use in the quantitative determination of reducing sugars in the urine, according to the Somogyi Carbonate Method, described in this issue. The comparator consists of a series of seven permanent color standards representing 0.5% to 6% reducing sugar in steps of 1%, mounted in a sturdy hardwood comparator block. Light is evenly dispersed through standards and specimen by means of a milk glass plate built into the back of the apparatus. In use, a specimen which has been heated with 10% sodium carbonate solution, is compared with the permanent standards in the comparator. Test tubes of selected uniformity should be employed for the specimen to assure accurate results.

- No. L26-500—Urine Sugar Comparator, Somogyi, as described above, complete with seven standards and three "Pyrex" brand glass test tubes selected for uniformity . . \$10.00
No. L24-160-S—Test Tubes Only, "Pyrex" brand glass, with inside uniform diameter of 14 mm. Dozen \$0.42

Injection? Inunction? Orally?

Ciba MALE SEX HORMONES

Now in 3 Convenient Forms

PERANDREN* "Ciba" represents a chemically pure and synthetic testosterone propionate, the most potent androgenic substance known. Supported by an important clinical literature. In ampules of 5, 10 and 25 mg. for injection.

PERANDREN OINTLETS* are individual-dosage tubes each containing 4 mg. of testosterone propionate in a bland unguent base. Administration is uniform, clean, easy.

METANDREN* is Ciba's orally administered synthetic, crystalline, chemically-pure methyltestosterone. Male sex hormone efficiency demonstrated in animals and humans. Scored tablets, 10 mg. each.

Indications:—**PERANDREN** is used in disturbances of male sexual development such as cryptorchidism, hypogonadism, dystrophia adiposogenitalis; also when impotence, sterility, male climacteric and prostatism are due to androgenic deficiency. For females, in some menorrhagias, metrorrhagias, dysmenorrheas, and to inhibit post-partum lactation. **PERANDREN OINTLETS** and **METANDREN** may be used in conjunction with or as substitute therapy for **PERANDREN** where the physician deems this logical.

*Trade Mark Reg. U. S. Pat. Off. Word "Perandren" identifies the product as testosterone propionate of Ciba's manufacture. Word "Metandren" identifies the product as 17-methyltestosterone of Ciba's manufacture. OINTLETS designate Ciba's ointment tubes containing accurate doses.

**Eliminates visual error
in hemoglobin matching**

**The Dick-Stevens Photoelectric
HEMOGLOBINOMETER**

Laboratory workers will appreciate the accuracy and ease of results with this new instrument. Use of a photoelectric cell eliminates visual error in matching. Described by Dr. George F. Dick and Dr. Daniel S. Stevens in the *Journal A. M. A.*, March 23, 1940. This apparatus is the result of a long period of development work at the University of Chicago Department of Medicine.

An important advantage of the instrument is that repeated readings on the same specimen give identical results. Besides hemoglobin, cell volume, sulfanilamide and sulfapyridine determinations can be made with the instructions and calibration tables furnished. Employs either inexpensive disposable plastic or permanent glass cells. For 110 V., A.C., 60 cycles. PRICE—\$75.

THE BUSIER YOU ARE
THE MORE YOU APPRECIATE
BALANCED GLASS

When the demands upon your laboratories are greatest you appreciate Balanced Glass most. For this is the ideal laboratory glass—the all-around glass. You turn to it confidently, sure of its strength, certain of its stability, and positive of its thermal resistance. All of these properties are *balanced* one against the other. Not one has been enhanced at the expense of another. All are present in the desired proportion for virtually any laboratory work. All are *combined* for maximum value—maximum laboratory usefulness.

In these days when time is such a factor, when tests, reports, and findings are more urgent than ever, standardize on Balanced Glassware. Always specify Pyrex brand Laboratory Ware, the only glassware made of Pyrex brand Chemical Glass, the Balanced Glass. Available from your regular laboratory ware dealer.

"PYREX" is a registered trade-mark and indicates manufacture by

New 1941 Model Harwood Rotary Microtome

Price Now Reduced to \$67.50

The Harwood Microtome has been completely revised and is now offered with a universal clamp securely holding object blocks up to one inch, and allowing the object to be rotated. The ruggedness and rigidity of the 1941 model makes it suitable for cutting all paraffin sections encountered in routine use. The positive mechanical feed is held under spring tension and is warranted not to skip or wear. The off-center knife clamp prevents the object from contacting the knife center and hence permits use of a greater portion of the edge by reversing the knife in the clamp. The adjustable clamp accommodates standard microtome knives.

No. JL19-285—Microtome, Harwood Rotary 1941 model, without knife.
Each \$67.50

A NEW, ENLARGED AND COMPLETELY REVISED "PYREX" LABORATORY GLASSWARE CATALOG

*Presenting 358 New Items
and Two New Lines*

VYCOR BRAND LABORATORY WARE

PYREX BRAND FRITTED WARE

• This new 160-page Catalog is the most comprehensive listing of laboratory glassware we have yet published. It lists approximately 2700 items of which 358 are new. Included is a complete listing of the items available in the new PYREX brand Fritted Ware, as well as the VYCOR brand Ware fabricated from the new 96% silica glass No. 790.

Prices have been reduced on a number of items. Consumer quantity discounts apply to practically all items when ordered in full original packages, except for a few items which are packed one piece per package.

Further economies can be realized if ware is purchased in assortments of 20, 50, or 100 original packages. All items listed are available through your regular laboratory supply dealer.

New Serological Baths for the Kahn Verification Test With Built-in Pipette Compartment

These new serological baths have been especially made for use in the Kahn Verification Test, according to the author's specifications. Two types are offered: an electric Warm Bath for use at 37° C., (which may be used for temperatures up to 60° C.), and a Cold Bath for use at 1° C. with ice. The Warm Bath consists of a well-insulated inner chamber measuring 16 x 19 inches, with a perforated shelf for accommodating serological tube racks in the usual manner. The shelf rests

on two pipette compartments with doors opening on the exterior front of the bath. A precision hydraulic thermostat with an expansion element in conjunction with a positive-acting magnetic switch maintains the temperature within 1/2° C. No micro switches are necessary for the thermostat employed. The Cold Bath is similar in all respects to the Warm Bath, but has no heating elements. In use, cracked ice with water is placed over the removable inner shelf causing cold water to surround the pipette chambers.

- JL4-994—Kahn Verification Serological Water Bath, for 37° C., complete with electric immersion heating element, thermostat, etc., for 110-120 volts A.C. or D.C., Each \$140.00
 JL4-995—Kahn Verification Test Water Bath, for 1° C., Each 75.00

For Assurance

The process industries, in many cases, live and sell on the results of a chemical analysis. Profit and loss, therefore, frequently become a matter of "drop by drop" analysis.

Kimble Blue Line Exact Burettes are an accepted standard in modern laboratories. They serve as infallible guards wherever control and analysis are important factors.

For Assurance, specify **BLUE LINE EXACT**.

Eliminates visual error in hemoglobin matching

The Dick-Stevens Photoelectric HEMOGLOBINOMETER

Laboratory workers will appreciate the accuracy and ease of results with this new instrument. Use of a photoelectric cell eliminates visual error in matching. Described by Dr. George F. Dick and Dr. Daniel S. Stevens in the *Journal A. M. A.*, March 23, 1940. This apparatus is the result of a long period of development work at the University of Chicago Department of Medicine.

An important advantage of the instrument is that repeated readings on the same specimen give identical results. Besides hemoglobin, cell volume, sulfanilamide and sulfapyridine determinations can be made with the instructions and calibration tables furnished. Employs either inexpensive disposable plastic or permanent glass cells. For 110 V., A.C., 60 cycles. PRICE...\$75.

CENCO LOW-TEMPERATURE INCUBATOR

The incubator consists of the latest model of a well-known electric household refrigerator, chosen by performance tests for its adaptability to regulated low temperature work, into which an especially constructed temperature control unit is placed. This unit raises the temperature level established by the refrigerating unit to the level for incubating and maintains it constant within a variable of approximately $\frac{1}{2}^{\circ}\text{C}$. It consists of a heating unit operated by a bimetallic thermoregulator through a relay circuit and an electric air-circulating fan, all of which are placed into operation by means of an on-and-off toggle switch on the control panel. Adjustment of the operating temperature is made by turning the thermoregulator control knob. The incubator is white enameled on the outside and porcelain finished on the interior. Two large shelves provide adequate space for 120 No. 29000 B. O. D. Bottles. The entire electrical system operates from 115 volt 60 cycle alternating current. Dimensions, over all: Height, 55 $\frac{7}{8}$ inches; width, 30 inches; depth, 27 in.

Morrison Sedographic Blood Sedimentation Apparatus

For obtaining precise photographic records of the complete twelve-hour blood sedimentation curve as described in this issue, *Journal of Laboratory and Clinical Medicine*. Consists of a metal housing with outside dimensions of 5 x 11 x 14 inches, with mercury vapor light source and revolving drum provided with a rule mask, and rotated by means of a synchronous motor. The center portion of the apparatus into which the sedimentation tube is placed is thermostatically controlled for maintaining the temperature at 37-½ degrees C.

L3-200—Blood Sedimentation Apparatus, Morrison Sedograph. Without photographic paper, but with three Morrison Sedimentation Pipettes, Mercury Vapor Lamp, Drum adjustment Knob, cord and plug, for operation on 110 volts. A. C.
Each \$97.50

*The Popular Centrifuge
of Intermediate Size—
with a twenty year record*

The *Size 1, Type SB Centrifuge* is a most popular model, of intermediate size, because it has ample capacity and speeds for routine hospital laboratory work. Many have been in constant service for twenty years with the *original International features* such as the brush release and brake mechanism, protective starting and low voltage release on rheostat, the flexibly mounted universal motor and the indicating tachometer.

THE
INTERNATIONAL
SIZE 1, TYPE SB CENTRIFUGE

Features:

- Speeds to 5,000 r.p.m., depending upon equipment used.
- Capacity to 1 litre.
- Adaptable to wide variety of accessory equipment.
- Practically vibrationless, with motor cushioned in rubber.
- Brush release and hand brake.
- Indicating Tachometer.
- 50 step speed control.
- Fully enclosed motor—for added safety.
- Portable stand of rigid construction.

THE SILVER ANNIVERSARY NUMBER

We Celebrate Our Silver Anniversary

The twenty-fifth volume of *THE JOURNAL OF LABORATORY AND CLINICAL MEDICINE* is completed. This issue inaugurates a second quarter century of service to medicine.

Twenty-five and more years ago no single medical periodical adequately filled the gap between laboratory research and the application in the field of clinical medicine of those discoveries coming from this research. This *JOURNAL* was inaugurated primarily to serve as the connecting link between the laboratory and clinical medicine. Clinical pathology was then in its infancy. Common interests developed with those who were applying laboratory methods to clinical investigation. The *JOURNAL* soon became the standard medium for presentation of advances in clinical pathology.

In the first volume the section on Laboratory Methods was written by the editors, as critical reviews. It soon became apparent that this department was the only available classified medium for the presentation of new laboratory techniques and apparatus. Contributions became so numerous that in the second volume the editors discontinued their review contributions.

With the appearance of Volume XI original contributions to the section on Laboratory Methods required so much space that it was deemed advisable to inaugurate an additional department, Selected Abstracts and Reviews. With this, the *JOURNAL* could still call the attention of the readers to new advances.

The Editorial Section continued with longer reviews, but as the *JOURNAL* grew, the volume of good material submitted was so large that the interval between the time of acceptance and the date of publication became too long. To provide more space editorials were discontinued in Volume XXI.

Major emphasis through the twenty-five years has been on laboratory medicine. At the same time, to retain broad perspective, a reasonable proportion of purely clinical articles have been regularly accepted. As a rule, contributions with direct clinical application have received precedence, although a number which might be classed under pure research have been published, especially when

the editors have recognized the possibility of future use in clinical laboratory medicine. In this way the JOURNAL has helped to facilitate the application of pure research to clinical problems.

The JOURNAL has served another function, important for medical progress. From time to time it has opened its pages to new medical societies whose fields of interest combined the laboratory and the clinic, that they might have a medium for presentation of their transactions until they could organize and support their own periodicals. This service has been given to The American Society of Clinical Pathologists, The American Association for the Study of Allergy, and The American Rheumatism Association.

The editors in celebration of the JOURNAL's twenty-five years of service, believe that, instead of reviews of medical progress during that period, a symposium discussing most recent developments and their probable future implications would be more consistent with the past and present policy of facilitating the progress of research. This Anniversary Issue looks forward, not backward. For this reason, it has seemed appropriate to celebrate the event at the inauguration of the second quarter century, in Volume XXVI, rather than at the end of Volume XXV.

The editors express their deep appreciation to the authors who have contributed to the Anniversary Number. They hope that their readers will derive as much satisfaction from perusal of these pages as they have in their preparation. They believe that the subjects discussed will become increasingly important. Special effort has been made to avoid repetition of discussions which are readily available elsewhere. This applies, for example, to the sulfonamide compounds.

The make-up of the JOURNAL has been altered from time to time to provide for needs as they have arisen. A journal whose function is to mirror progress should not be static; it should experiment with new methods of presenting subject matter, with full realization that some of the trials may be unnecessary or unsatisfactory. In this event, there will be no hesitancy in altering or abolishing them.

The commencement of a second quarter century of publication is an appropriate time to put some of these tentative ideas into effect. To this end the JOURNAL announces certain additions to its departments.

Clinical chemistry has assumed steadily increasing importance in laboratory medicine. Articles in this field have been scattered in the departments devoted to Clinical and Experimental Investigation and Laboratory Methods. It is believed that a separate department of Clinical Chemistry will focus interest in this field and will facilitate classification of the material presented. The new department of Clinical Chemistry will be edited by Dr. Victor C. Myers and Dr. Edward Muntwyler of Western Reserve University.

The number of letters discussing editorial reviews of medical progress has in the past made the editors deeply conscious of the interest which they have stimulated. It is regretted that space limitations required their discontinuance. Believing that progress reviews of this type serve a real function, the editors of the JOURNAL will again inaugurate reviews, but with a new, and it is hoped improved, method of approach.

The men best qualified to write progress reviews are those who are themselves conducting pioneer investigations in the fields. From time to time there will appear, therefore, as leading articles, invitation contributions on subjects analogous to those presented in this Anniversary Number, and written by outstanding investigators. If these adequately fill a need, they will be made regular sections of the JOURNAL.

The importance of good illustrations has been recognized from the outset. The JOURNAL's excellent photographic reproductions have been an outstanding feature. Not only has medical illustration become a specialty in its own right, but with the improvements of the last decade in precision photography, the physician often illustrates his own articles. Many have found photography a pleasant hobby and a useful one, since it can be used in connection with one's work.

The *Journal of the Biological Photographic Association* serves those deeply interested in scientific photography. Not limited to medicine, it covers all fields of science.

The editors are of the opinion that a small department of medical illustration, covering photographic and other methods, will be of sufficient concern to those readers now interested in photography, or to those who may become interested, to justify its establishment. This department, by broadening interest in the subject and providing an alternate medium for publication, will not compete with the *Journal of the Biological Photographic Association*, but will complement it and provide a classified department on other methods of medical illustration. It will be inaugurated in January under the editorship of Carl D. Clarke, Professor of Art as Applied to Medicine and Director of the Department of Art of the University of Maryland Medical School, who organized and first edited the *Journal of the Biological Photographic Association*.

During its existence the JOURNAL has grown from approximately 950 pages of Volume I to over 1,300 pages in Volume XXV. The new departments will require either the addition of about 400 pages or some limitation on the nature of subjects now considered appropriate for acceptance. Suggestions and constructive criticism on this point and on other subjects herein discussed, but particularly with regard to any subject matter in the last few volumes which may have been of interest to too small a proportion of the readers to justify its publication, are welcome.

The editor expresses his deep appreciation to all the writers who have contributed to the JOURNAL during his seventeen years of editorship, and to those whose earlier papers were accepted by the first editor; writers whose contributions have given life to the JOURNAL and enabled it to serve adequately as a functionary in the progress of medical knowledge.

WARREN T. VAUGHAN

THE AUTONOMIC NERVOUS SYSTEM CONSIDERED IN RELATION TO EXPERIMENTAL AND CLINICAL PHENOMENA*

DENNIS E. JACKSON, PH.D., M.D., CINCINNATI, OHIO

IN A MANNER characteristic of the history of our times a contemporary wag has defined an adult as one who has stopped growing at both ends but continues to grow in the middle. This conception of a generalized entity composed of two ends and a middle, in either division of which growth, or at least change, may occur, coincides very well with our present conception and knowledge of the autonomic nervous system. Within recent years many changes, and a good deal of growth, have occurred in our understanding of this system. But not infrequently a change which at first appeared as growth has ultimately been found to be merely an added source of confusion. And in many respects our knowledge of the involuntary nervous system is still in an infantile or even an embryonic state. Current medical literature contains hundreds of references to such subjects as renin, renin-activator, angiotonin, ischemin, sympathin E and sympathin I, and intermedin; the carotid and aortic bodies and the corresponding sinus structures; choline-esterase, amine oxidase (see "sulfosynthase"), adrenergic and cholinergic nerves, benzedrine, veritol, corbasil, "933F," prostigmine, paredrine, beta-erythroidine, and trasentin and trasentin-6H; failures frequently following surgery on the sympathetic nervous system because sensitization to adrenalin develops at the nerve endings; the remarkable and peculiar symptom complexes which occur in the presence of pheochromocytomata; desensitization to food proteins by prolonged administration of mechoyl; the strange and often depressing mental and physical manifestations resulting from disturbances of the hypothalamus and related structures—these and numerous other new and unexpected experimental or clinical observations all tend to reveal the vast territory which the autonomic nervous system is rapidly usurping in the field of modern medicine. The names "sympathetic," "autonomic," "involuntary," and "vegetative" are often (but not quite correctly) used synonymously in referring to this system.

Anatomically the autonomic nervous system is considered to consist of two parts, the true or thoracicolumbar sympathetics emerging from the eighth cervical, and the thoracic and lumbar (to the third or fifth) divisions of the spinal cord, and the parasympathetics which pass out from the central nervous system in the third, seventh, ninth, and tenth cranial nerves and from the second to the fourth sacral segments of the cord. These primary emerging fibers are preganglionic, and they pass through greater or lesser distances to communicate with the nerve cells of the postganglionic fibers. The postganglionic fibers are highly specialized both as regards their anatomic dis-

*From the Department of Pharmacology of the University of Cincinnati Medical College, Cincinnati.

tribution and their individual functions. All these fibers are efferent in character (see below for sensory counterparts).

Returning to the structural conception of two ends and a middle, we may note that centrally the autonomic nervous system primarily originates in nuclei in the hypothalamus and in the medulla. But these centers have numerous connections, often unknown or at best only vaguely surmised, with higher divisions of the brain or with other neighboring nervous mechanisms. Mystery surrounds much of the workings of the hypothalamus, but it undoubtedly exercises a dominant control over many, perhaps most, of the functions of the autonomic nervous system. Through the hypothalamus and medulla impulses from above permit mental stresses or strains or other psychologic states, generally entirely unconsciously, to exert their influences on the more distal portions of the autonomic nervous system. Drugs may affect all these regions and the pharmacologic interpretation of these reactions may be exceedingly difficult, and especially so if the effects are obscured, as would usually be the case, by more peripheral actions. If pathologic conditions in the hypothalamus, or in higher related structures, produce serious mental or physical changes, one can only conjecture as to how drugs may act on these structures in order to be therapeutically valuable to the patient.

In recent years, a vast amount of work has been done to explain the actions which take place at the peripheral endings, both of the preganglionic and of the postganglionic neurones. Already one Nobel prize has been granted for work in this connection. Perhaps there is still room for another. When impulses pass outward over preganglionic fibers, both true sympathetic and parasympathetic, these impulses arrive in due course at the endings of these neurones around the nerve cells of the postganglionic neurones. At this point each impulse is now presumed to cause the liberation of a minute quantity of acetylcholine which transmits the excitation to the next receptor, that is, the cell of the postganglionic neurone in this case. The liberated acetylcholine lasts for only the briefest instant of time, and then it is equally rapidly hydrolyzed by cholinesterase which is always present due to its wide distribution in the tissues. An exactly similar action is also believed to occur in striated muscles when nervous impulses pass out from the central nervous system over the cerebrospinal motor nerves to striated muscle nerve endings. All preganglionic nerve endings, and all parasympathetic nerves whose endings are thus stimulated by acetylcholine, are designated as cholinergic. If eserine in small quantity is applied to these endings previous to stimulation of the nerves, it is presumed to take up and destroy a certain amount of the esterase normally present. Thus, when a nerve impulse passes down the nerve fiber and liberates a charge of acetylcholine, the action of the latter will be prolonged as manifested in the muscle or gland cell by its increased or prolonged activity. In certain instances, such as the sweat glands, nerve fibers which anatomically belong to the thoracolumbar sympathetics are cholinergic in action and pharmacologically react as do the parasympathetic nerves.

For many years a queer problem was presented by the results following electrical stimulation of certain true sympathetic nerve fibers. In some cases

smooth muscle contracted, in others it relaxed. When adrenalin was found to produce similar results, it was surmised that there must be some difference in the chemical constitution of those muscles, yet no analyses could demonstrate this. A little later on a considerable shifting of viewpoints led to the almost universal use of adrenalin to detect the presence or absence of true sympathetic nerve endings. But the problem of contraction in some cases and inhibition in others still remained. Within recent years, however, a number of new conceptions have been advanced in the hope of explaining these phenomena. It is now presumed that impulses passing down the true sympathetic nerves (except those which are cholinergic in nature) cause the liberation of adrenalin (Dale) at the terminal endings of these fibers, and that this adrenalin transmits the excitation to the muscle or gland cell. Cannon and his co-workers have advanced the view that either adrenalin or some similar substance is liberated by the nerve impulses, and that this substance at once unites with one or the other of two substances (E and I) already present at the nerve endings to form sympathin E (effector) or sympathin I (inhibitor). If strong stimulation of the nerve leads to formation of excessive amounts of either sympathin E or sympathin I, then this may be carried away in the blood stream (or perfusion fluid) and produce corresponding results on other similarly innervated tissues. Nerves of this character are designated as adrenergic.

The method by which adrenalin is inactivated in the body has been a standing question. Gaddum and Kwiatkowski¹ (1938) have advanced the view that adrenalin is oxidized in the body by amine oxidase. As supporting evidence of this, they note that ephedrine increases the action of adrenalin and also that ephedrine inhibits the action of amine oxidase. This view corresponds to that of the action of choline-esterase and eserine as they affect the action of acetylcholine.

Opposed to this view, recent admirable work has been published by Richter² in which he finds that adrenalin is excreted in the urine in a conjugated (sulfate ester) form. This conjugation probably takes place largely in the liver, and while some adrenalin may be oxidized by amine oxidase, still conjugation is a more rapid process and is probably the method by which most of the adrenalin disappears from the body. The conjugation is effected by the "sulfosynthase" system which is responsible for the conjugation of sulfate with phenols in the body. The liver is particularly effective in removing both adrenalin and phenols from the circulating blood. Since polyphenols use up "sulfosynthase" in the process of conjugation, it might be expected that administration of polyphenols, together with adrenalin, would lead to an augmentation and prolongation of the action of the adrenalin. This has been shown to occur. In a general way, therefore, the interactions of eserine, choline-esterase, and acetylcholine in the cholinergic system would correspond to polyphenols, "sulfosynthase," and adrenalin in the adrenergic system.

A further interesting point has also been brought out by Richter. It has generally been stated that adrenalin is only slightly, if at all, active when

taken by stomach. Richter has found that adrenalin is active when administered orally and will produce, over an extended period, the usual actions of the drug, but in a less acute degree. As adrenalin is ordinarily taken by mouth, most of the drug is oxidized in the gut. This oxidation can be mainly avoided by taking the adrenalin (e.g., dose 15 mg. adrenalin) with 0.1 Gm. glycine and 10 c.c. of 1 per cent acetic acid in 50 c.c. of water; up to 70 per cent of the adrenalin thus taken has been recovered (in conjugated form) in the urine. No free adrenalin has been found in the urine, and the presence of the drug cannot be detected until the conjugated drug has been hydrolyzed by boiling (the urine) with sulfuric acid. After purification and proper chemical manipulations the recovered free adrenalin gives a positive reaction with as many as seven chemical and color tests and also produces inhibition of isolated strips of intestine. It has also been shown that corbasil, epinine, and d-adrenalin, as well as l-adrenalin (the natural form), are all eliminated in the urine in corresponding conjugated forms. In all these cases the derivatives formed are apparently the sulfate esters, and conjugation occurs on one of the phenolic hydroxyl groups. This method of inactivation of sympathomimetic amines probably holds good also for many other members of the group, but not for all.

It has been the usual custom to consider the autonomic nervous system as a purely and solely efferent or motor system. But it must be fully recognized that there is a sensory counterpart in most, if not in all, autonomic actions. The sensory impulses which initiate autonomic motor effects are transmitted centrally over sensory fibers belonging to the cerebrospinal system. These fibers have their sensory cells in the posterior root ganglia of the spinal nerves or, in the case of the cranial nerves, in the corresponding sensory ganglia on the course of these nerves, such as the Gasserian ganglion on the fifth nerve and the ganglion jugulare and the ganglion nodosum on the tenth nerve. Throughout life enormous numbers of sensory impulses must be constantly passing into the central nervous system from most of the organs and structures of the body. These impulses set up numerous reactions in the sympathetic nervous system that must very generally be considered as reflex in nature. Some of these reflexes may be fairly simple in character, but others are extraordinarily complicated. Clinically they may represent the nervous mechanisms involved in an endless variety of aches, pains, swellings, indigestion, cardiac irregularities, blood pressure changes, secretory disturbances, metabolic or temperature variations, etc.

It was observed by Dale many years ago that an injection of adrenalin, following a sufficient dose of ergotoxine intravenously, caused a fall in blood pressure instead of the usual rise. This was interpreted as being due to a paralysis of the vasomotor constrictor nerve endings by the ergotoxine, so that following this adrenalin could only stimulate the vasodilator endings which ergotoxine was presumed not to paralyze. Rothlin arrived at the conclusion that ergotoxine, at least in large doses and in some locations, had a paralyzing action on certain sympathetic inhibitory endings as well as upon the motor endings.

In recent years various observers have obtained different reactions in tissues by a number of different drugs when different anesthetics were used. In certain instances this phenomenon may be very striking; perhaps it has not been sufficiently appreciated in the older investigations of sympathomimetic drugs. A relatively new preparation, "933F" (F stands for Fournau who introduced the substance) piperidomethyl-3-benzodioxane, has been found to have a paralyzing action on sympathetic endings similar to that of large doses of ergotoxine. Small doses of ergotoxine stimulate motor sympathetic nerve endings like adrenalin, but large doses paralyze these endings.

Page³ and his co-workers have recently made a number of interesting observations on the vasopressor substance obtained from the kidney. This substance is called renin, but renin is not active until it has combined with an activator contained in the blood, and this combination (of the two substances) has been named angiotonin. Crystalline derivatives have been prepared from angiotonin which is an active vasopressor substance. It appears to act pharmacologically in a manner similar to that of pitressin. Another substance obtained from the kidney by Prinzmetal, Lewis, and Leo⁴ also has a vasopressor action and has been named by them ischemin. The chemical constitution or identity of these preparations has not yet been worked out. One can only speculate at the present as to what relationship, if any, these kidney products may bear to clinical hypertension. There appears to be some connection between the action of these preparations and the influences which the central nervous system exercises over chronic hypertension. The sympathetic nervous system is probably involved in the pathologic reactions necessary to the maintenance of this state. The work of Goldblatt and the recent experiments of Dock⁵ throw some light on the still obscure problems here involved.

Marraszi⁶ has recently advanced the view that adrenalin, or an adrenalin-like substance, produces inhibition when present in minute (but sufficient) quantities (generated at the inhibitory endings) in the synapses in sympathetic ganglia. This counteracts the stimulating effects of acetylcholine which is generated at the (motor) synapses in these ganglia when nerve impulses from the cord or brain reach the ganglia. Experimentally adrenalin (or sympathin) may be produced in the body in sufficient quantity to bring about this type of inhibition by stimulating the nerves to the adrenal glands or other sympathetically innervated organs.

A generation or so ago hopes were held out that a careful study of the chemical structure and formulas of drugs would ultimately lead to a rational explanation of how they act. In particular, a careful comparison of the formulas of related substances, such as the sympathomimetic amines like adrenalin, tyramine, epinine, etc., was expected to throw great light on the prediction of how any given compound would act in the body even without trying it out. This was a kind of biochemical conception of pharmacology. To what vagaries and delusions this line of reasoning may lead one is well illustrated by observations made by Koppanyi and his co-workers⁷ relative to the so-called vasomotor reversal produced by ergotoxine or ergotamine with reference to the rise or fall produced in the blood pressure by adrenalin when different

anesthetics are used. These authors found that ergotamine or ergotoxine in doses of 0.2 to 4.0 mg. per kilogram in cats usually produces vasomotor reversal to adrenalin under urethane, but not under barbiturate anesthesia. In the latter, the adrenalin pressor effects were usually increased in height and always in duration. Thus urethane anesthesia constitutes the most favorable, and barbiturate narcosis the most unfavorable, condition for the elicitation of vasomotor reversal to adrenalin. Under barbiturate narcosis there is a distinct synergism between epinephrine and the ergot alkaloids. Blood pressure rises produced by adrenalin are often higher after ergotoxine or ergotamine than from control injections, and are always more prolonged. Massive doses of ergotoxine or ergotamine in barbiturate narcosis diminish or abolish the rises from epinephrine without producing reversal. Physostigmine or prostigmine facilitates vasomotor reversal under urethane anesthesia, while large doses of atropine administered before the ergot alkaloids in urethanized animals prevent reversal by epinephrine. Kappany and his collaborators further find that since the action of a single effective dose of ergotamine lasts for several hours, it is possible to produce vasomotor reversal under urethane anesthesia, and after recovery from urethane to administer a short-acting barbiturate and produce in the same animal a potentiated, instead of a reversed, epinephrine effect. Conversely, it is possible to use a short-acting thiobarbiturate, such as pentothal, and obtain a potentiated epinephrine response following ergotamine, and after the recovery of the animal from the barbiturate, to give urethane and obtain a vasomotor reversal to adrenalin. Thus the difficulty of determining how or where a single member of a series of compounds acts is seen. The complications will increase when predictions for other members of the series, or for entirely different drugs which have similar pharmacologic actions, are attempted.

Barbiturates⁸ appear to depress or paralyze the vagus ganglia in the heart. Pilocarpine or acetylcholine may still slow the heart, while eserine may restore the excitability of the vagus but may not spontaneously slow the heart rate.

Actions mediated partly or entirely through the autonomic nervous system may be so extensive and involved that one cannot fathom all the changes that may be taking place at a given moment. But by special experiments in which only a small number of reactions may be studied at any one time, a fairly complete, composite picture may usually be built up to explain any special phenomenon as a whole.

One of the simpler autonomic reactions is that by which the systemic blood pressure is raised in the presence of asphyxia. The asphyxia may be produced in many ways, but experimentally stoppage of the respiration by electrical stimulation of a vagus nerve is perhaps the most common. Fig. 1 shows the effects of asphyxia, not by vagus stimulation, but by stoppage (twice) of the respiration (which was artificial) in a curarized dog. When the respiration was stopped (at "off"), asphyxia quickly developed. The blood pressure promptly rose. This was due primarily to stimulation of the aortic body by lack of oxygen in the blood (hypoöxia), but also partly to the stimulating action of

carbon dioxide in the venous blood on the vasomotor center in the medulla, and to some further stimulation (by the hypoöxia) of the carotid body. Sensory (chemo-) reflexes pass from the aortic body (over the vagus nerve) and from the carotid body (over the branches of the sinus nerve) to the medullary centers in which the necessary readjustments are made, so that efferent impulses can be sent out over the true sympathetic system to cause the rise in blood pressure. Resumption of respiration (at "on") quickly causes a return to normal as the blood is again reoxygenated.

Fig. 1.—For discussion see text.

Fig. 2 shows the action of paredrinol on the walls of the nasal sinuses and passages, on the blood pressure, and on the respiration. Here marked stimulation of the vasoconstrictor nerve endings caused a prompt and prolonged constriction of the vessels in the walls of the nasal passages (nose record) and a rise in blood pressure. As the blood pressure rises, the heartbeat becomes slower (increased pulse pressure shown by the mercury manometer tracing), until finally, at the highest point, the pressure suddenly drops and an extended series of very slow beats ensue. These slow beats are due primarily to the reflex action of the carotid sinus nerves. These nerves (endings) are stimulated by the increased tension (stretch) in the walls of the carotid sinuses, and impulses are quickly sent to the medullary center from which reflex impulses are sent to the heart over the inhibitory vagus fibers. These slow the heartbeat. A vasodilator action (not identifiable in this record) may also have been present but concealed by the peripheral action of the drug. See also discussion of Fig. 12.

Fig. 2.—For discussion see text. The nose cannula was made by means of a tumbour connected with rubber tubing to one nostril into which a short piece of glass tubing was inserted (airtight). The other nostril was closed tightly by means of a clamp. The soft palate was held firmly pushed back against the posterior wall of the nasopharynx by means of a soft rubber ball attached to the end of a metal rod. The free end of the rod rested tightly against the upper incisor teeth, and the whole rod was held in place by means of a clamp which closed over the rod and around the animal's nose. This arrangement held the posterior nasal cavity closed airtight, so that changes in the vessels of the walls of the sinuses and air passages could be readily recorded by air transmissions to the tumbour.

Fig. 3.—For discussion see text

Fig. 3 shows actions similar to those of Fig. 2, but in Fig. 3 paredrine was injected and the inhibitory action of the carotid sinus reflex was very much more extended. Artificial respiration was being carried out in this experiment, and this may have influenced the depth of the anesthesia somewhat. The more lightly the animal is anesthetized, the more active the inhibitory reflexes are likely to be. Formerly this vagus inhibitory action (slow heartbeat) was supposed to be due entirely to mechanical stimulation of the inhibitory center in the medulla by increase in intracranial pressure from the marked vasoconstriction produced (peripherally) by such drugs. Carotid reflexes have been found by various investigators to be greatly reduced, or abolished entirely, by certain anesthetics such as ether and most of the barbiturates. Clinically one might consider whether or not such an action would be beneficial or otherwise to a patient who was anesthetized for an operation.

Fig. 4.—For discussion see text.

Fig. 4 illustrates the action of propadrine. A slight stimulation of the respiratory rate is present here, and it is often much more marked, for this and various other members of the sympathomimetic amines often stimulate the central nervous system in addition to their peripheral actions.

Fig. 5 illustrates the action of benzedrine. It should be noted here that the drug was injected into the femoral vein. This is far removed from the mucous membranes of the nasal passages, yet these membranes show an immediate shrinking. The constriction of these vessels is exactly analogous to that which occurs in the kidney or spleen.

Fig. 6 shows the action of neosynephrin, but in this case a striking abnormality in the respiration is noted. This change is a variety of Cheyne-Stokes respiration and is due to the effects of the anesthetic (nembutal) rather than to the neosynephrin. The interrelations between the blood pressure and the respiration should be noted.

Fig. 5.—For discussion see text.

Fig. 6.—For discussion see text. A section of the record was omitted between the two parts here shown.

Fig. 7.—Here nembutal dilated the vessels in the nasal walls. Drugs which stimulate the medullary center, or asphyxia, may act in exactly the opposite manner, and cause constriction of these vessels. For discussion see text. Also see discussion of Fig. 11.

Fig. 7 demonstrates a variety of autonomic effects. At the beginning of the tracing injection of 3 c.c. of nembutal solution leads to a marked dilatation of the vessels in the nose. This is perhaps partly peripheral but mainly central in action. It may also be partly due to ganglionic paralysis, for Koppányi¹⁸ has noted that the vagus ganglia in the heart are paralyzed by barbiturates. It is to be noted (near the middle of this record) that stimulation of the right (intact) vagus caused only a slight inhibition of the heart. The sympathetic fibers to the nose (with their synapses in the superior cervical ganglion) were still able to produce a nasal vasoconstriction. Pare-drine still produced its normal reaction. In the cervical region in dogs the sympathetic nerves for the head run (peripherally but up into the head) in the vagus trunks. Hence stimulation of the vagus trunk causes vasoconstriction in the nasal walls.

Fig. 8.—For discussion see text.

Figs. 8 and 9 show the action of parasympathetic drugs. The first record shows the effects of two injections of acetylcholine bromide. The rapid recovery from large doses is evident. This is due to rapid destruction of the acetylcholine by esterase at the endings of the vagi nerves in the heart and also in the lungs, for the bronchi are strongly contracted by this drug.

Fig. 9 illustrates the action of arecoline (after nicotine) on the post-ganglionic terminations of the vagi nerves in the heart. This leads to a marked inhibition and weakening of the heart with a corresponding fall in blood pressure, producing an asphyxia which is still further increased by bronchial constriction. The animal resists this asphyxia by increasing and greatly accelerating its respiratory efforts. This results in a somewhat obscuring effect on the respiratory tracing which was made by a tambour connected with a side tube of the tracheal cannula.

Fig. 10 illustrates the ganglionic type of autonomic action. Nicotine first stimulates and then, if the dose is large enough, paralyzes all autonomic ganglia. Acetylcholine (Fig. 8) also has this ganglionic ("nicotine") action, but its peripheral (cholinergic) "muscarine" action may generally over-

Fig. 9.—For discussion see text.

Fig. 10.—For discussion see text.

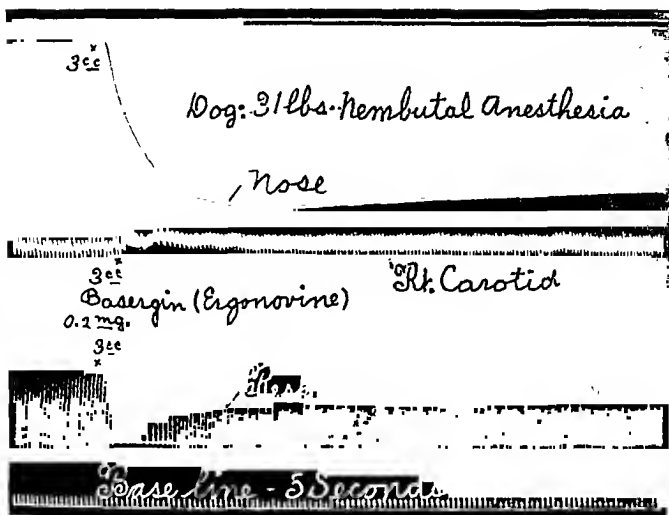

FIG. 11.—For discussion see text.

FIG. 12.—For discussion see text. The stomach record was made by a device attached to the pyloric end of the stomach. Contraction is the upward movement.

shadow its ganglionic action. The primary vagus ganglion stimulation is not very evident in Fig. 10, because the dose of nicotine was so large that these ganglia were paralyzed before their inhibitory effects on the heart could be recorded.

In Fig. 11 the action of an ergot alkaloid (basergin, ergonovine) is illustrated. The marked contraction of the vessels of the nose may be largely due to central stimulation as a result of the asphyxia produced by depression of the respiration. This shows the roundabout methods by which the autonomic mechanisms are frequently brought into action. But ergot alkaloids also have a peripheral action resembling that of adrenalin. In this record, however, the slight change in blood pressure rather indicates a different origin for the nasal constriction in which most of the systemic arterioles did not take part.

Fig. 12 demonstrates an entirely different action from any of the other drugs, yet its resemblance to the other records is so close that one must be impressed by the nature of the mechanisms involved. What appear to be very slow beats (carotid sinus inhibition) along the higher parts of the blood pressure tracing are more likely in this instance to be due to extraventricular systoles. This type of action may also occur with the true sympathomimetic amines, and with both types of drugs carotid and aortic sinus reflexes may also occur. With barium, however, the stomach shows marked contraction (muscle stimulation), while with adrenalin-like drugs inhibition generally occurs except at the sphincters (and even these have an obscure innervation).

Barium and some other metals, posterior pituitary extracts (pitressin, pitocin), probably angiotonin, histamine, nitrites, and various other drugs act on smooth muscle to produce either stimulation or depression. These actions are generally considered to be directly on the muscle fibers. Probably the peripheral actions of some anesthetics should be included here. It seems quite possible, and even probable, that some, and maybe all, of these drugs really do effect their actions through nervous elements or receptors which are not yet understood. There are special indications for this view, especially in the case of posterior pituitary extracts.

The nature of the points on which sympathomimetic drugs act has long been discussed. Earlier workers called these points "end plates" or simply "nerve endings." Later the term "myoneural junction" was introduced, and finally the word "receptor." The history of the changing viewpoints which these terms have signaled in the past forty years constitutes one of the most interesting chapters in the records of modern medicine. The very recent introduction of the conception of adrenergic and cholinergic nerve endings paves the way for another, perhaps equally evanescent, chapter.

There are still many obscure phenomena connected with the pharmacology and physiology of the autonomic nervous system; and probably mechanisms of great importance connected therewith have not yet even been surmised. The very recent discovery of the special significances of the carotid and aortic bodies and sinuses, the meanings of which are still far from being completely understood,⁹ serves well to illustrate this. From the standpoint of pathology,

Fig. 13.—Diagrammatic representation of the autonomic nervous system. The parasympathetics are (mostly) shown on the left while the thoracolumbar (true) sympathetics are shown on the right. Note the color scheme to differentiate between adrenergic and cholinergic fibers. (From Jackson: *Experimental Pharmacology and Materia Medica*.) Figs. 1 to 12 illustrate actions at all points at which drugs may affect the autonomic nervous system with the possible exception of some centers in the hypothalamus or other parts of the brain and cord

a mere beginning has been made. Not infrequently one may stand in the presence of the direst clinical phenomena, and feel and see dimly as if in a dream, or sometimes as if in a nightmare, that the symptoms he observes must of necessity be largely, if not completely, due to actions of the autonomic nervous system. And yet as death hovers near, or even seizes the victim, the most astute physician may sometimes not be able to determine what mechanisms are involved, let alone cure the patient. Fatal attacks of angina pectoris, or the origin of the obscure and sometimes fatal attacks in the presence of pheochromocytomata, and probably other causes of death not now recognized clinically, may serve to illustrate this point.

A considerable number of clinical conditions are now known or believed to bear a more or less direct relationship to the autonomic nervous system. Among these may be mentioned vasomotor rhinitis, bronchial asthma, urticaria, angioneurotic edema, colic in hollow visceral organs, motor disturbances of these organs, hiccups, angina pectoris, disturbances of cardiac rhythm, migraine, diabetes insipidus, pyrexia, hypertension, and the like. Undoubtedly a number of others should be added even though their relationship to the autonomic nervous system may not be known until far in the future.

The ancients were accustomed to orient their historical perspective of civilization with reference to their seven wonders of the world. Modern man has added many more wonders. Yet not one of these, either ancient or modern, presents a more remarkable phenomenon than do the actions of some of these drugs on the autonomic nervous system, such, for example, as the action of 1 or 2 mg. of atropine or adrenalin when injected intravenously into a man weighing as much as 150 pounds.

INTERACTION OF VITAMINS AND DRUGS WITH CELL CATALYSTS*

FREDERICK BERNHEIM, PH.D., DURHAM, N. C.

TO THE clinician and physiologist the results obtained with isolated enzymes and tissue suspensions may seem to have only remote application to the processes in the human and intact animal. It is the purpose of this review to correlate, in certain selected instances, the physiologic and pathologic findings in man and animals with what is known of the concomitant changes in tissue metabolism and the catalysts involved.

In the first part, four vitamins will be considered. Each of these vitamins, or its derivative formed in the body, combines with a specific protein and this combination is an enzyme, the absence of which in deficiency states causes metabolic disturbances which may partly account for the accompanying symptoms. In the second part, drugs will be discussed which either (a) combine with specific enzymes, thereby inhibiting their normal catalytic activity, or (b) are attacked and rendered pharmacologically inactive by enzymes.

PART I

Thiamin: (a) Carbohydrate Metabolism.—The work on thiamin may be divided into two parts. The first definite evidence about the nature of the disturbance in the central nervous system in thiamin deficiency was obtained by Peters.¹ He showed that the minced optic lobes of the pigeon with beriberi were unable to oxidize pyruvic acid and that the addition of small amounts of thiamin in vitro restored the oxidation. Lohmann and Schuster² identified the substance necessary for the decarboxylation of pyruvic acid by yeast as thiamin pyrophosphate. This is also the active form in the animal body,³ which combines with a specific protein to form the enzyme which oxidizes pyruvic acid to acetic acid.

It follows from this that pyruvic acid should accumulate in the blood of thiamin-deficient animals. This has been shown for pigeons⁴ and man,^{5,6} although in the latter other keto acids beside pyruvic are also present. Feeding thiamin reduces the keto acid level of the blood to normal. That pyruvic acid is a normal intermediate in carbohydrate metabolism in man was shown by Johnson and Edwards,⁷ who found high values in the blood after severe exercise. The impairment of this important phase of carbohydrate metabolism in thiamin deficiency probably accounts for the decreased glucose tolerance.⁸ The relation of thiamin to insulin and diabetes is still not clear.

It is not surprising to find a close relationship between thiamin and the thyroid because of the marked effect of this gland on carbohydrate metabolism. There are no in vitro experiments to explain the exact mechanism of the interaction, but the experiments on animals show clearly that thiamin counteracts the toxic action of thyroxine,⁹ prevents weight loss¹⁰ and loss of liver glycogen¹¹

*From the Department of Physiology and Pharmacology, Duke University School of Medicine, Durham.

in thyroid-fed rats, and is helpful in the preoperative treatment of Graves' disease.¹² Conversely, thyroid feeding increases the thiamin requirement of dogs¹³ and depletes the thiamin in the kidney and liver of rats.¹⁴

(b) *Interaction with Acetylcholine.*—The central nervous symptoms of beriberi can be explained by the disturbance in pyruvic acid metabolism. The edema can also be explained on this basis because the pyruvic acid metabolism of the kidney, and consequently kidney function in general, is very sensitive to thiamin deficiency.¹⁵ It is difficult, however, to explain on this basis the loss of appetite, achlorhydria, loss of tone in the gastrointestinal tract and arterioles, and tachycardia, especially as pyruvic acid in concentrations found in beriberi has no toxic action.¹⁶ The following experiments with thiamin and acetylcholine offer a possible explanation for these symptoms. (It is not the purpose of this review to enter into the debate on the exact function of acetylcholine in nervous transmission. It is generally agreed, however, that acetylcholine is produced at most synapses and myoneural junctions, and it follows that a disturbance in acetylcholine metabolism will be reflected in the tissues supplied by cholinergic nerves. The enzyme cholinesterase specifically hydrolyzes acetylcholine.)

Thiamin augments the action of acetylcholine on the blood pressure of the cat and on the isolated rat intestine.¹⁷ It sensitizes various nerve trunks to electrical stimulation,¹⁸ and it is liberated when cholinergic nerves are stimulated electrically.¹⁹ Most of these effects could be explained on the basis of cholinesterase inhibition by thiamin. Thiamin does inhibit the cholinesterase,²⁰ although a relatively large concentration is required. There exists the possibility that, because of physical conditions or local concentration effects, thiamin, *in vivo*, does control cholinesterase activity. Its affinity for the enzyme is twenty-six times that of acetylcholine. But whatever the mechanism of the interaction between thiamin and acetylcholine, such interaction can explain the cardiac and gastrointestinal symptoms of thiamin deficiency, symptoms which can be relieved temporarily by choline esters. Also part of the protective effect of thiamin in hyperthyroidism may be due to its inhibiting action on the serum cholinesterase, which is higher than normal in patients with this disease.²¹

Riboflavin.—Warburg and Christian¹ first demonstrated the catalytic importance of riboflavin in yeast. As a phosphate ester² attached to a specific protein, it forms an enzyme which oxidizes cozymase (see under nicotinic acid) which in combination with another protein is reduced by hexose phosphate. Its importance in animal metabolism was shown when riboflavin was identified as vitamin G.³ Recent *in vitro* work on various oxidases of animal origin have shown that dinucleotide derivatives of riboflavin, rather than riboflavin itself, form important enzymes when combined with specific proteins. These dinucleotide derivatives are decreased in the heart and liver (but not in the brain and kidney) of rats on flavin-deficient diets and are rapidly synthesized when pure riboflavin is fed.⁴ The following enzymes, which are found in a variety of tissues, contain a flavin dinucleotide: Diaphorase 1 and 2 which oxidize reduced cozymase (coenzyme I) and coenzyme II^{5, 6} and which are in turn oxidized through an intermediary by the cytochrome-cytochrome oxidase system; xanthine oxidase, which oxidizes xanthine and hypoxanthine to uric acid

and oxidizes aldehydes to acids;⁷ and d-amino acid oxidase which oxidizes the "nonnatural" isomers of the amino acids to keto acids.⁸ Other less well-defined enzymes have also been described.

It follows that the activity of these enzymes should be diminished in flavin-deficient animals. This has been shown in the rat for xanthine oxidase and d-amino acid oxidase.⁹ The over-all oxygen uptake of tissues taken from flavin-deficient rats is, however, little affected, with the exception of the diaphragm which is increased 30 per cent¹⁰ and the skin which is decreased 37 per cent.¹¹ This latter finding may account for the characteristic alopecia and dermatitis in rats and the cheilosis and seborrheic lesions in man.^{12, 13} The general weakness, fall in body temperature, sudden collapse in deficient dogs,^{14, 15} and lack of growth in rats and chicks¹⁶ can conceivably be explained by the impairment of certain essential oxidases. It is more difficult to explain the cataract¹⁷ and corneal vascularization¹⁸ in rats, the intestinal hemorrhage,¹⁵ and degeneration of the axis cylinders in the posterior columns in dogs¹⁹ on this basis. These symptoms may be the indirect expression of a general metabolic disturbance. There is also no explanation for the effect of riboflavin on the regeneration of hemoglobin in the anemic dog.²⁰

Nicotinic Acid.—Warburg and co-workers¹ first demonstrated the biologic importance of nicotinic acid when they showed that its amide was part of a compound containing as well two pentose, one adenine, and three phosphate molecules. They named this substance coenzyme II and showed that, in combination with a specific protein, it formed an enzyme which oxidized a hexose phosphate. The sugar was oxidized by reducing the coenzyme which in turn was reoxidized by an enzyme containing riboflavin (see under riboflavin). Nicotinic acid amide was then shown to be a part of coenzyme I^{2, 3} which differed from coenzyme II in having one less phosphate molecule and which was identical with cozymase, the substance that Harden and Young⁴ many years previously had shown to be essential for the fermentation of yeast. One or the other of the coenzymes has been found to be essential for the oxidation of important metabolites, for example, lactic acid⁵ which requires coenzyme I. (The oxidation of lactic acid thus needs a nicotinic acid derivative, which in turn needs a riboflavin derivative, and the pyruvic acid formed from the lactic acid then requires thiamin for its oxidation.)

When nicotinic acid was found to be the specific cure for black tongue in dogs⁶ and for pellagra in human beings,⁷⁻⁹ the possibility arose that some of the symptoms might be explained on the basis of a low coenzyme concentration in the tissues, with a consequent impairment of metabolic processes. Since no chemical methods were available for the estimation of the normally very small amounts of coenzymes present in tissues, Kohn¹⁰ devised a biologic test based on the fact that *H. parainfluenzae* required coenzyme I and/or II for growth.¹¹ Although this test seems specific for the two coenzymes, there remains the possibility that other similar, but as yet unknown, compounds may act as growth factors for these bacteria. With this method, the normal coenzyme value of human blood was determined, and it was shown that all the coenzyme was carried in the corpuscles. The value for pellagrins was within the normal range. This was confirmed later in a larger series of cases,¹² and Axelrod and asso-

ciates^{12a} obtained similar results. The low values obtained by Vilter, Vilter, and Spies¹³ for pellagrins might be explained by their use of different bacteria, or by the fact that their results were expressed in terms of whole blood instead of corpuscles. Kohn was also able to show that the oral administration of nicotinic acid rapidly raises the coenzyme concentration in the red blood cells of normal subjects and pellagrins.

Further investigation of this finding¹⁴ showed that human corpuscles were able to synthesize coenzyme from nicotinic acid *in vitro* and that they were then able to oxidize lactic acid more rapidly. The inability of Vilter, Vilter, and Spies¹⁵ to obtain this synthesis of coenzyme from nicotinic acid with washed cells is explained¹⁶ by the fact that their method of washing definitely injures the cells.

The fact that the blood of human pellagrins showed no marked variation from normal in coenzyme concentration made it necessary to study the concentration in the tissues. For this the black tongue dog was used.¹⁷ It was found that the coenzyme of the liver was reduced 70 per cent and that of striated muscle 35 per cent in black tongue, but that other tissues had normal values. These results, which were confirmed by Axelrod and associates,¹⁸ indicate that the liver was sacrificing its store of coenzyme to maintain the level in other tissues. The oxygen uptake of the isolated liver tissue was, however, increased 35 per cent (see oxygen uptake of diaphragm in riboflavin deficiency).

No symptom of black tongue or pellagra can be directly explained on the basis of impaired metabolism caused by deficiency in coenzyme. It is always possible that the symptoms are an indirect expression of such an impairment, but the *in vitro* results leave open the possibility that nicotinic acid may have other functions in the body.

The concentration of coenzyme in the blood has been measured in a variety of diseases. It tends to be low in diabetes^{12, 19} and high in pneumonia,¹² but it is normal in cardiovascular and gastrointestinal disturbances.¹² It is very low in tumor and embryonic tissue.^{20, 21}

Vitamin A.—Of the various actions of vitamin A in the animal, the only one that has been elucidated by *in vitro* experimentation is its action in the eye. The relationship of diet to night blindness was recognized by a number of investigators, but was clearly stated by Bloch.¹ Fridericia and Holm² and Holm³ were able to show that the regeneration of visual purple after bleaching with light took place more slowly in vitamin A-deficient rats which were night blind. The normal pig eye was then found to be one of the richest sources of vitamin A.⁴ The correlation between a low concentration of vitamin A in the blood and night blindness in human subjects was made by Sic.⁵ Numerous dark adaptation tests have been made^{6, 7} in an attempt to use this as a measure of vitamin A deficiency, and it has been shown⁸ that administration of vitamin A to human subjects deficient in vitamin A causes rapid improvement in their dark adaptation.

The exact part that vitamin A plays in rod vision and its relation to rhodopsin (visual purple) was first elucidated by Wald.^{9, 10} He was able to show that the following cyclic mechanism occurs. Illumination rapidly bleaches rhodopsin even in solution extracted and separated from the retina, and the yellow

pigment retinene is formed. Some of the retinene can be directly reconverted in the dark into rhodopsin, but some is converted into vitamin A. These two reactions occur to a slight extent in solution but take place readily in the isolated retina. The vitamin A formed is then slowly reconverted into rhodopsin. This reaction, however, occurs only in the intact eye, where rhodopsin, retinene, and vitamin A are all loosely combined with protein.

This mechanism explains not only the night blindness in A deficiency, but also the rapid dark adaptation following an intense flash of light on the dark adapted eye. During the short flash, a large amount of retinene accumulates, but relatively little is converted to vitamin A. In the dark, retinene is rapidly converted into rhodopsin. After long illumination a steady state is reached with a small amount of retinene and a relatively large amount of vitamin A which is now the main source of the rhodopsin. Since this conversion is relatively slow, dark adaptation after prolonged illumination should be slower than after the short flash, and experimentally this is found to be so. According to the Janesos,¹¹ the pigmented epithelium converts vitamin A into rhodopsin which then migrates into the rods, and retinene migrates from the rods to the pigment cells where it is converted into vitamin A.

Wald¹² was also able to show that mammals and salt-water fish use vitamin A₁, whereas fresh-water fish use vitamin A₂ in their visual cycle. The differences in the absorption bands of A₁ and A₂ are carried over when they are converted into rhodopsin and porphyropsin, respectively, and into retinene 1 and 2. From the chick eye, which is almost completely made up of cones, Wald¹³ has extracted another pigment, iodopsin, which is also a protein-carotenoid complex. It seems probable that vitamin A plays some part in the cones of the human eye, as several investigators^{8, 14, 15} have found that cone and rod thresholds vary in the same way in vitamin A deficiency.

PART II

Eserine (Physostigmine) and Prostigmine.—Dale,¹ Brown,² and Cannon³ have reviewed the evidence that the production of acetylcholine is part of the mechanism for synaptic and myoneural transmission. The cholinesterase, which hydrolyzes acetylcholine into choline and acetic acid, thus making it inactive, is an intimate part of this mechanism. It follows that any drug that inhibits the activity of this specific enzyme and thus allows acetylcholine to accumulate in vitro may have definite effects when injected into the animal. In assessing how far the in vitro effects are paralleled by the in vivo action of such drugs, the distribution of the drug in the body and the consequent inhibition of the esterase in situ must be taken into consideration. For instance, two drugs may inhibit a solution of esterase to the same extent, but when injected into the animal, one may cause excitation, the other depression (see below), either because their locus of action is different or because different amounts of acetylcholine are allowed to accumulate. In most ganglia, acetylcholine in small amounts causes excitation; in larger amounts, depression.^{4, 5}

Kahane and L  vy,⁶ using the single drug, eserine, showed that the effects of various choline esters in the body were potentiated by eserine in proportion to the rapidity with which the different esters were hydrolyzed by the cholinesterase.

terase. But when several drugs and one ester were used, there was no correlation between the extent of the inhibition *in vitro* and the potentiating effect *in vivo*,⁷ presumably because the drugs varied in their ability to penetrate to the enzyme *in situ*. Such considerations may also explain the results of Schweitzer and Wright⁸ who showed that eserine increases reflex excitability in the cat and that prostigmine depresses it.

Despite this and other minor variations, the effects of eserine and prostigmine injected into the animal closely parallel the effects of acetylcholine, and in all cases potentiate the effects of the latter. This has been shown for the human eye,⁹ respiration in cats,¹⁰ sympathetic ganglia,⁷ mammalian skeletal muscle,¹¹ the human gastrointestinal tract,¹² when injected into the ventricles of man,¹³ and on the T-wave in the dog heart.¹⁴ Clark and Raventos¹⁵ have shown that the action of eserine on the frog heart can be accounted for quantitatively by its inhibition of the esterase. Eserine and prostigmine, when injected, decrease the esterase activity of the circulating blood as has been demonstrated many times in myasthenia gravis. (For the literature on the treatment of this disease by prostigmine, see reference 16. The symptoms of myotonia are increased by injection of prostigmine¹⁷).

Morphine.—The effect of various centrally acting drugs on the cholinesterase of the brain has been investigated.¹⁸ Morphine and apomorphine were found to cause significant inhibitions in low concentrations. Because intraventricular injections of acetylcholine in man¹¹ and injections into the hypothalamic regions in cats¹⁹ usually cause nausea and vomiting, it is possible that morphine and apomorphine may produce these effects through the accumulation of acetylcholine in regions affecting the vomiting center. Kuhn and Surles²⁰ investigated other compounds of the morphine group and found a parallelism between the central emetic action and the inhibitory effect on the esterase *in vitro*. Moreover, emetine was the only other drug tested that inhibited the enzyme in equivalent concentrations. The blood and tissue cholinesterase was inhibited in the same way by these drugs. Besides giving a possible explanation for the central emetic action, this inhibition by morphine could also explain its other effects in the body, such as the slowing of the heart, increase of spinal reflexes, and spasticity of the intestine with constipation. Recently, Slaughter and Gross²¹ and Slaughter and Mimsell²² have confirmed these findings and have shown that the inhibition occurs *in vivo*. They have also shown that eserine potentiates the action of morphine and that with small doses of eserine it is possible to decrease the therapeutic dose of morphine by half. This suggests that sensory impulses may also be mediated by acetylcholine. The fact that strychnine²³ also inhibits the cholinesterase may explain how it increases the spinal reflexes. Its other effects which differ from those of morphine may well be explained on the different distribution of these two drugs in the body.

Amines (Except Histamine), Adrenaline, and Sympathomimetic Substances. An enzyme which specifically oxidizes certain amines was first isolated from the liver and studied by Hare¹ and Bernheim.² It was thought that this enzyme had a protective function in the liver in oxidizing amines formed by bacterial decarboxylation of amino acids in the intestine. The aldehydes formed from this oxidation which were no longer pharmacologically active could re-

enter into normal metabolic processes. The fact that animals, in which the cecum is large, as in the guinea pig and rabbit, have large concentrations of this enzyme in their livers supports this idea, as does the fact that mesecaline, the active principle of the Mexican cactus (*Anhalonium lewinii*), is also oxidized by the enzyme.³ In this case an acid is formed which is identical with that isolated from the urine of men fed mesecaline.⁴ The finding of amine oxidase in the brain⁵ and in a number of other tissues,⁶ and the identification of the adrenaline-oxidizing catalyst⁷ with it⁸ suggest other functions for this enzyme.

Because of the two hydroxy groups in the ortho position in the benzene ring, adrenaline is an autooxidizable compound which in oxygen is oxidized to a melanin-like substance. It was thought that this oxidation accounted for the evanescent effects of injected adrenaline. It was shown, however, that body fluids, such as blood and lymph,⁹ extracts of heart,⁹ extracts of uterus,¹⁰ and mixtures of amino acids,¹¹ especially cysteine and glutathione,¹² delay or prevent this oxidation. The amine oxidase, therefore, may be important for the oxidation of adrenaline, although its affinity for the enzyme is low.¹³ The products of the oxidation are ethylamine and an aldehyde which is inactive.¹⁴ The two hydroxy groups are not oxidized by the enzyme. It has been suggested¹⁵ that the amine oxidase may oxidize the adrenaline-like substances (sympathin) produced at certain postganglionic sympathetic nerve endings, although its presence at such endings has not yet been demonstrated. Ephedrine and benzedrine inhibit the amine oxidase,¹⁶ and it is possible to explain their peripheral action on this basis, i.e., the prolongation of sympathetic effects.

The amount of central excitation produced by benzedrine, ephedrine, and allied substances closely parallels the amount of inhibition produced by them on the amine oxidase in vitro.¹⁴ This raises the question of the function of the amine oxidase in the brain. Mann and Quastel¹⁷ have shown that aldehydes formed from the oxidation of amines such as tyramine markedly inhibit the respiration of the brain. Benzedrine, by inhibiting the amine oxidase, prevents the production of such aldehydes and thus increases the brain respiration and may thereby produce excitation. This explanation assumes that small concentrations of aldehyde regulate directly or indirectly central excitation, and conversely that an increase in the amount of aldehyde may lead to narcolepsy and similar depressed states.

An attempt has been made to show that the potentiating action of cocaine and related substances on the sympathetic system is due to the inhibition of the amine oxidase by these drugs.¹⁸ Inhibition has been found to occur, but only in the presence of exceedingly high concentrations of these drugs. It is possible that the enzyme in situ is more sensitive.

Other mechanisms for the oxidation of adrenaline have been suggested. It is oxidized to form a red pigment, adrenochrome, by certain dehydrogenases, and the pigment in turn is oxidized by the cytochrome system.¹⁹ This may be the mechanism of the "pyrocatechol oxidase" investigated by Heirman²⁰ and Baer²¹ which oxidizes adrenaline to adrenoxine, a compound that lowers the blood pressure of rabbits and slows the frog heart.²¹

Histamine.—Although the original finding of Barger and Dale¹ of histamine in the intestinal mucosa raised the question of whether it was actually present

in the cell or formed by the methods of extraction, it is now recognized as a normal constituent of most cells.² In the dog³ the largest concentration of histamine is in the duodenum, lung, and liver, respectively. Within the cell it apparently has no pharmacologic action, but when released into the blood it gives many symptoms of shock. With modern micromethods for its estimation, the concentration of histamine in the blood in various conditions has been measured. Blood under normal conditions contains very small amounts. It is increased in perfusates from the lungs of sensitized guinea pigs⁴ and from the lungs of guinea pigs perfused with snake venom,^{5,6} staphylococcus toxin,⁷ and peptone.⁸ It is increased in the blood of dogs and guinea pigs during anaphylactic shock^{9,10} and insulin shock¹¹ and is released from tissues injured by various chemical and physical agents.¹² Its concentration is high in the blood of patients with migraine, asthma, urticaria, and other allergic diseases,¹³ and when injected, it increases migraine headache, probably by increasing the pulsations of the pial and dural arteries.^{14,15} Histamine will cause spontaneous contractions in the isolated auricle of the guinea pig¹⁶ and is produced continuously by the dog heart,¹⁷ the amount produced being a function of the work done by the heart.¹⁸ Its production by the normal heart, however, has been questioned.¹⁹ It is also produced by active skeletal muscle,²⁰ by sensitized red blood cells *in vitro*,²¹ and in the skin by painful stimuli.²²

The presence of an enzyme in tissues that inactivates histamine was first described by Best and McHenry²³ and studied by McHenry and Gavin.²⁴ Recently it has been studied in detail,^{25,26} and it has been shown to produce ammonia and hydrogen peroxide and to require oxygen for its action on histamine. It also oxidizes cadaverine and putrescine,²⁷ and the name *diaminoxidase* has been proposed for it instead of the original *histaminase*. The enzyme is rapidly inactivated by acid and by trypsin and pepsin.^{26,28} It is present in the tissues of most animals, and in man the kidney has more than the liver.²⁹

Preparations of the enzyme given twelve hours before the antigen to sensitized guinea pigs decreases the severity of the anaphylactic shock,³⁰ and it has been claimed that histaminase in the blood of allergic patients is lower than normal.³¹ A commercial preparation from the intestinal mucosa called *torantil* has been used for various allergic conditions, especially serum sickness^{32,33} and hypersensitivity to cold.^{34,35} It is given in salol-coated pills to prevent its destruction by acid in the stomach, and on liberation in the intestine it must be rapidly absorbed into the mucosa to prevent its destruction by trypsin. In the mucosa it may lower the concentration of histamine by oxidative deamination, and thus lower the concentration in the blood, which presumably is higher than normal in allergic cases. The best preparations of the enzyme act very slowly *in vitro*, requiring twenty-four hours at 37° C. to oxidize 1.0 mg. of histamine. Any rapid improvement cannot be expected from the administration of the enzyme, and further work is required before its clinical value can be definitely established. Equivocal results with the enzyme have recently been obtained.³⁶

Because of lack of space, no discussion is possible of the enzymes in tissues that hydrolyze atropine and homatropine³⁷ and acetanilid,³⁸ or of the effect of various anesthetics on the enzyme systems of the brain.³⁹

COENZYMES I AND II IN HUMAN BLOOD*

S. P. VILTER, PH.D., M. B. KOCI, B.A., AND T. D. SPES, M.D.
CINCINNATI, OHIO

INTRODUCTION

FOR many years the two dietary deficiency diseases, canine blacktongue and human pellagra, have been regarded as analogous syndromes. The belief that both of them might result from a deficiency of the same chemical substance or substances was supported by the fact that the symptoms of both diseases were relieved by the administration of liver extract.^{1,2} In 1937 Elvehjem, Madden, Strong, and Woolley³ isolated the amide of nicotinic acid from liver extract and reported that it was this substance in liver extract which cured blacktongue in dogs. Following this observation, nicotinic acid and, later, nicotinic acid amide were used clinically with spectacular success in the treatment of human pellagra.⁵⁻⁷

Naturally, the striking clinical results from the use of nicotinic acid and nicotinic acid amide in the treatment of pellagra have led to increased interest in the respiratory coenzymes I and II, cozymase and coferment,[†] respectively, which are known to contain nicotinic acid amide. These coenzymes are, by definition, specific organic catalysts which are relatively heat-stable, dialyzable, and which retain activity when separated from the living cell. Each is specifically necessary in an enzymatic reaction, and each is produced by living cells from nicotinic acid amide, ribose, adenylic acid, and phosphoric acid.

A general survey of the literature during the past thirty-six years shows notable advances in scientific knowledge dealing with coenzymes I and II. Harden and Young (1906)⁸ found that a dialyzable fraction of boiled yeast juice stimulated alcoholic fermentation. Later Meyerhof (1918)⁹ showed that these coenzymes occurred also in muscles and animal organs and that they could function in vitro to increase the respiration of fresh minced muscles. It was not until 1932, however, that nicotinic acid amide was isolated from the purest preparations of these coenzymes.^{10, 11} The present knowledge of the chemical constitution of coenzymes I and II indicates that these substances

These studies were aided in great part by grants from the John and Mary R. Markle Foundation and E. R. Squibb & Sons.

†In this paper, coenzyme I will be designated frequently as cozymase, and coenzyme II, as coferment. Other names for coenzyme I are diphosphopyridine nucleotide D.P.N., or codehydrogenase I; similarly, other names for coenzyme II are triphosphopyridine nucleotide T.P.N., or codehydrogenase II.

We are very grateful to Professor H. von Euler, Biochemiska Institutet, Stockholm, Sweden, for samples of pure cozymase; and to Herr Geheimrat Doctor Otto Warburg, Kaiser Wilhelm Institut für Zellphysiologie, Berlin-Dahlem, Germany, for pure coferment and pure cozymase.

differ chemically in their content of phosphoric acid, but are similar in that both are pyridine nucleotides which are indispensable for carbohydrate and protein metabolism.

The principles involved in the problem of the stimulation, cessation, or inhibition of cellular growth have been studied in a number of ways. It is perhaps wise to review briefly our present thoughts on this matter. We consider that the growth and respiration of cells, of which rapidly growing bacteria are excellent examples, involve the synthesis of complex substances from simpler compounds and the organization of these substances to form protoplasm. The pattern of growth is attended by numerous side reactions and energy changes which occur at body temperatures and therefore must be catalyzed. This physiologic catalysis can take place only with the aid of metallic ions, specific enzymes of a protein nature, and certain crystalloidal organic substances which work with the enzymes and are designated coenzymes. In many instances, coenzymes can be synthesized by lower forms of life as is true in the case of most strains of the dysentery bacillus, the growth of which can actually be used as a measure of the amount of nicotinic acid amide or nicotinic acid (coenzyme I and II precursors) which is present in the medium. Other organisms, such as the influenza bacillus, differ in that they require coenzyme I and II preformed in order to grow. Accordingly, we can obtain a measure of the enzymatic growth factor in tested material by bacterial growth, and thus obtain an index of the amount of the substance present, when, and only when, the specific bacterium is unable to synthesize the essential substances.

METHODS AND MATERIALS

Since the methods for studying coenzymes I and II in the blood are not simple and are not always satisfactory, several methods have been tried in this laboratory: (1) A specific biologic method for the determination of coenzyme, using yeast, "Koehsaft" (fluid obtained from blood and soft tissue after extraction with boiling water for two minutes), and a manometric apparatus;^{12, 13} (2) a chemical test for pyridine nucleotides, in which a colorimetric test for nicotinic acid amide is used before and after hydrolysis of the test material; by this method the increased amount of nicotinic acid amide found after hydrolysis can be calculated in terms of either coenzyme or coferment;¹⁴ (3) two bacteriologic methods using the growth properties of either *B. influenzae* or *B. parainfluenzae*^{15, 16} for the estimation of the total concentration of coenzymes I and II and possibly of unknown substances with similar properties.

A bacteriologic method¹⁵ has been used chiefly by us because it seemed that the principles concerned with the metabolism of these living bacterial cells were similar to those which govern the metabolic changes in the cells of the human body. The following detailed information concerns the method as originally published,¹⁵ with a number of modifications.

The Reproducibility of the Method.—The reproducibility of the method has been tested by making from six to ten determinations on the same blood, using the same medium and culture. The dilutions of blood in broth varied from 1:1,000 to 1:12,000 as has been reported previously,¹⁵ and the series of dilutions included several dilutions closely spaced near a previously determined

end point of growth. In these tests, the growth regularly stopped at the same dilution, as was determined by several observers, and the sharp end point occurred where the dilutions of blood were from 10 to 15 per cent apart. Therefore, the largest error possible was ± 15 per cent.

Computations Based on Visual Comparisons.—Along with the series of experiments described above, standards were prepared from ten concentrations of von Euler's purest cozymase (0.01 to 0.003 $\mu\text{g.}$ per cubic centimeter in the basal medium), and the tubes were inoculated from the same culture. After a twenty-four-hour period of incubation, the tubes containing the cozymase standards and the test determinations on blood were examined visually before a direct light. The tube that contained the highest dilution of blood which supported visible growth was matched with the tube containing cozymase standard most nearly identical in optical density. The blood dilutions factor, e.g., 8,000, was multiplied by the concentration of cozymase, e.g., 0.005 $\mu\text{g.}$ per cubic centimeter, in the selected standard, and the result expressed as cozymase equivalents per cubic centimeter of whole blood (40 $\mu\text{g.}$ per cubic centimeter). Next, from five to ten determinations were made on blood samples from seven normal persons, and the results were compared with a cozymase standard as before. The average error of these determinations was ± 8 per cent.

The term "cozymase equivalents" has been used¹⁷ to indicate that all the coenzyme-like substances in blood which function as factor V for *Hemophilus parainfluenzae* can be calculated arbitrarily as cozymase equivalents. We have adopted this estimation for the determination of coenzymes I and II with the influenza bacillus. This calculation is useful, but the proof that coenzymes I and II can act interchangeably in all reactions and to the same extent as growth-limiting factors (factor V) for *H. parainfluenzae* and *H. influenzae* is inadequate; that is to say, in the proper medium (lacking only these coenzymes), and within certain ranges of concentration, the extent of growth (or more properly the rate of reproduction) of a twenty-four-hour culture of either of these organisms is dependent upon the quantity of either coenzyme, I or II, that is present.

Recovery of Cozymase.—In assaying the recovery of cozymase, the end point of growth in a normal blood was determined first in the routine manner. Twenty-four hours later another sample of the same blood was tested. The procedure for each sample was to prepare three laked solutions of the blood; the first was deproteinized¹⁸ without any further additions; to a second, 10 or 20 $\mu\text{g.}$ of cozymase were added just before the sample was deproteinized; and to a third, 10 or 20 $\mu\text{g.}$ of cozymase were added after the deproteinization. In six series of determinations where the dilutions near the estimated end point of growth were from 10 to 20 per cent apart, the end point of growth was the same whether the cozymase was added before or after deproteinization. The added cozymase which was recovered from different visual or photometric determinations varied from 80 to 95 per cent with several samples of cozymase.

Calculations Based on Photometric Comparisons.—As in the visual comparison of bacterial densities, photometric studies of the relation of the growth of *B. influenzae* in autoclaved hemopectone broth (which contains added hematin) have shown that only in a limited range of concentrations is the

growth proportional to the concentration of pure cozymase added. Even though there is blood present in the basal autoclaved medium, other factors affect the density of bacterial growth since large concentrations of fresh blood support a more luxuriant growth in the autoclaved blood-peptone broth than does an excess quantity of cozymase. In the higher dilutions of blood which support growth, however, the influence of these secondary factors appears minimal. Therefore, we consider the end point of growth to be a most sensitive test for the coenzymes (Fig. 1). As was suggested by Kohn¹⁶ for his standard yeast extracts, we have found that photometric comparison of the density of bacterial growth in dilution of blood with the turbidity of bacteria grown in

**BLOOD OF A NORMAL PERSON SUPPORTS GROWTH
OF *B. INFLUENZAE* TO $\frac{1}{6000}$ OR $\frac{1}{8000}$ IN
HEMOPEPTONE BROTH**

**BLOOD OF A CLINICAL PELLAGRIN SUPPORTS
GROWTH OF *B. INFLUENZAE* TO $\frac{1}{2000}$ OR $\frac{1}{4000}$**

Fig. 1.—Each row of tubes shows the sharp end point of the growth of *B. influenzae* which is supported by dilutions of blood in autoclaved hemopeptone broth. The first row of tubes contains aliquot portions of blood from a "normal" person, and the second row, comparable portions of blood from a patient with clinical pellagra.

standard cozymase solutions (0.01 to 0.003 μ g. per cubic centimeter of basal medium) has simplified the determinations and recoveries of the coenzyme equivalents in blood. A curve of the optical densities plotted against the concentration of the standard cozymase solution is of value, however, only for the day of the test, for the culture of *B. influenzae* varies slightly from day to day. We recommend either the preparation of two cozymase standards* each day to compare with points on a concentration curve so that the value of the cozymase equivalents in a dilution of blood which supports *B. influenzae* can be interpolated from the curve of turbidities and multiplied by the dilution factor to obtain the cozymase equivalents per cubic centimeter of blood, or a determination on "normal" blood. In the latter case one can use the calibration curve only for relative comparison.

Normal Values.—Values obtained in normal blood for arbitrary cozymase equivalents, determined by the two bacteriologic methods of estimation, are of

*At the suggestion of Dr. A. E. Axelrod, the standards were kept frozen, and it was found that under such conditions, they were more constant than at the temperature of the refrigerator.

"Normal" average of cozymase equivalents per cubic centimeter of whole blood = 31 μ g., or 3.1 mg. per cent.

"Normal" average of cozymase equivalents per cubic centimeter of packed cells = 69 μ g., or 6.9 mg. per cent.

somewhat similar order of magnitude." The values obtained here are remarkably consistent for any individual blood, using any single cozymase standard. We have found by the dilution and end point method and by photometric comparison of cozymase standards with the growth in higher dilutions of blood that normal values range between 20 and 50 μ g. of cozymase equivalents per cubic centimeter of normal blood, and between 55 and 85 μ g. per cubic centimeter of packed cells. The normal values, shown in Table I, have been obtained by photoelectric comparison in the Evelyn colorimeter of the growth of *B. influenzae* in accurately prepared serial dilutions of blood and in aliquots of a standard cozymase solution. The higher dilutions were used for the calculations, to minimize the effect of other growth-stimulating factors in fresh blood. Blood from a normal person was tested under identical conditions as a control for the experimental determinations.

CLINICAL APPLICATIONS

1. *Pellagra*.—In 1939, at the Hillman Hospital Nutrition Clinic, coenzyme studies with a bacteriologic method¹⁵ were made upon 145 selected cases of pellagra. Similar studies have been made upon 45 patients so far in 1940. Most of the subjects were ambulatory and subsisted on the deficient diets which are typical of the pellagrins in this clinic. For the purpose of special observations, some of these patients were hospitalized and maintained on glucose and water. These cases were selected for study because it was believed that they were deficient in nicotinic acid and might be lacking in the dinucleotides, co-

enzymes I and II, which contain nicotinic acid amide. In these studies, it was observed that the degree of the deficiency of coenzymes I and II in whole blood and in packed cells did not parallel the severity of any one of the pellagrous symptoms, but in general paralleled the clinical state of the patient. There were, however, a few noteworthy exceptions. Table II shows the results of the initial assay of 45 clinical and subclinical cases of pellagra and indicates that in pellagrins there is a decrease in the content of the coenzyme growth factor in the whole blood. In the anemic patients, there frequently is an apparent compensation for the lack of cells, so that the total coenzyme value per cubic centimeter of cells is much higher than in normal red blood cells (Fig. 2).

Fig. 2.—Relation of cozymase equivalents in whole blood and in packed cells. Figs. 2, 6, and 7 illustrate the various ways of considering the cozymase equivalents in blood. In this figure, the cozymase equivalents in the whole blood of three persons were essentially the same, whereas the percentage of packed cells varied in the three cases. Fig. 6 shows three cases where there was parallelism in the content of cozymase equivalents in whole blood and in the percentage of packed cells. In contrast, Fig. 7 shows that, with the same percentage of red blood cells in the blood of three persons, the cozymase equivalents in whole blood may vary considerably. These findings suggest that it is best to consider the coenzyme content of the blood as a functional unit rather than to set up arbitrary standards which may not always correlate with any particular determination of the formed elements of the blood.

In many of our mild cases the results are consistent with the results of Kohn and Bernheim,¹⁷ who found that, in nine cases of pellagra, the concentration of cozymase equivalents in packed cells was "only moderately low."* But if one compares the results in Table II with those in Table I, he sees that the concentration of the coenzymes in the blood of persons with optimal nutrition is consistently higher. It is to be noted also that nicotinic acid therapy produces clinical improvement, that it never fails to increase the content of the blood coenzymes in persons with uncomplicated pellagra, and that the ingestion of nicotinic acid by normal persons also increases the concentration of these substances in the blood.

2. *Diabetes Mellitus*.—Some years ago we learned that the administration of large amounts of glucose over a period of weeks to chronic pellagrins predisposed many of them to a recurrence of their disease. This observation, together with the knowledge that patients with diabetes mellitus not infrequently have pellagra, suggested that the metabolism of glucose is associated with the antipellagra factor and that patients with diabetes mellitus should be selected for a coenzyme study.

*Our experience with the culture of *H. parainfluenzae* has been limited to studies of normal and pellagrous blood. The particular culture of *H. parainfluenzae* for which we are indebted to Dr. Kohn is well suited to turbidity measurements in our hands, but the density of growth is proportional to the concentration of cozymase only in a limited range (0.01 to 0.003 $\mu\text{g.}$). This finding is similar to the observation which we have made using our culture of *H. influenzae*. For that reason we believe the highest dilution of blood used in this test to be the best index of the coenzyme content. As parallel studies using both methods have not always given comparable results, further investigations are in progress.

Ten cases of extreme diabetic acidosis, in addition to the three previously reported,¹⁸ were tested (1) before insulin therapy, (2) after insulin and glucose had been injected and the patients had regained consciousness, and (3) again after they were "regulated" on a diabetic diet without special vitamin preparations. The red blood cell count of these patients on admission ranged from 5,500,000 to 6,000,000 per cubic millimeter because of dehydration; the hematocrit values were above 50 per cent. In contrast, the coenzyme content of the blood was low on admission, with an average limit of growth in a dilution of 1:1,000. When the patients were "regulated" as to diet and insulin requirement, the red blood cell counts and hematocrit readings were lower, and the coenzyme I and II content of the whole blood was increased so that the average limit of growth after successful regulation of the same seven patients was 1:6,000. Kohn and Bernheim¹⁷ have reported partial confirmation of this observation as a result of their study of 23 regulated diabetic persons not in a state of acidosis. In a more recent study, Sydenstricker, Geeslin, and Weaver¹⁹

have shown clinically that a very delicate balance exists in certain diabetic persons who have subsisted for long periods of time on inadequate and unbalanced diets and who have frequent bouts of active pellagra. The use of increased quantities of insulin and glucose in these patients induced an exacerbation of their pellagrous symptoms.

Fig. 3.—Maximum blood dilutions of a patient with chronic lymphatic leucemia supporting growth of *B. influenzae*. This figure illustrates the low values for the coenzyme I and II content of the blood of persons who have severe leucemia. This particular patient had a spectacular increase in the coenzyme content of blood following oral administration of yeast. This increase paralleled the patient's greater strength and sense of well-being, although there were no demonstrable changes in the number or character of the cellular elements as seen in blood smears.

3. *Leucemia*.—Studies of the blood coenzyme values of patients with lymphogenous and myelogenous leucemia have not led to conclusive or consistent results. In 23 of 27 cases studied by us, the coenzyme values were found to be lower than normal, as was described in an earlier study.²⁰ In four selected cases of lymphatic leucemia, nicotinic acid, administered orally or intravenously, repeatedly failed to increase the level of the coenzymes. In three of the four cases the daily simultaneous injection of 25 mg. of nicotinic acid and 5 mg. of riboflavin induced a slight, but temporary, increase in the coenzyme level, but the oral ingestion of from 60 to 100 Gm. of brewer's yeast daily increased and maintained the coenzyme level for weeks (Fig. 3). Of these 27 cases, one patient, H. G., was admitted to the hospital with moist sores around the lips of several weeks' duration. After riboflavin (5 mg. daily) was given intravenously for five days, the sores healed and never returned throughout a six weeks' period of observation. Another interesting case in this group was F. H., who, when admitted to the hospital in extremis, had coexisting clinical pellagra. These two persons were the only ones of the group of 27 who showed clinical evidence of a specific vitamin deficiency.

4. *Pneumococcal Pneumonia*.—A recent report²¹ of 20 cases of pneumococcal pneumonia, which were studied before and after serum or sulfapyridine therapy, has shown that 17 of the 20 patients studied had blood coenzyme values which were below the lowest normal limits found during a simultaneous study of 50 normal persons. The low values rose spontaneously to normal in these 17 patients following the crisis of their disease.

5. *Roentgen Sickness*.—The study of the coenzyme content of blood was extended to persons who experienced acute but temporary roentgen sickness, because it had been observed²² some time ago that people receiving therapeutic doses of roentgen rays excreted abnormal quantities of a porphyrin-like pigment after exposure to the radiation. Studies on 10 selected patients receiving courses of deep roentgen therapy have shown a rapid decrease within twelve hours in the coenzyme I and II content of whole blood which was not associated with any change in the hematocrit²³ (Fig. 4). Normal levels per cubic centimeter of blood were obtained, however, on these same patients from twenty-four to thirty-six hours after the exposure. Unpublished results of Bean, Vilter, and Spies have shown that roentgen radiation of blood in vitro did not cause a decrease in coenzyme content.

Fig. 4.—Showing the decrease in the coenzyme I and II concentration of the blood of two "normal" persons following roentgen therapy, as shown by the growth of *B. influenzae* in aliquot dilutions of blood in hemopectone broth.

DISCUSSION

It has been shown in two laboratories^{15, 16} that nicotinic acid or nicotinic acid amide, given orally or intravenously, increases the measurable concentration of coenzymes I and II in the blood of normal people and pellagrins. Along with the increase in the blood, there is a concomitant increase in the normal excretion of nicotinic acid and of coenzymes I and II in the urine. In this clinic, low values for coenzymes I and II have been observed in the blood of selected patients with pellagra, diabetes mellitus, acute pneumococcal pneumonia, and roentgen sickness (Table III). These findings suggest that the administration of vitamin B concentrates or nicotinic acid to persons with other acute infections or metabolic disturbances might well be evaluated clinically in a large number of cases. The use of nicotinic acid is accepted in the treatment of pellagra and has been suggested in certain cases of roentgen sickness^{22, 24} and untoward sulfanilamide reactions.²⁵

The increase in coenzyme I and II content of the blood in patients with pellagra, pneumococcal pneumonia, diabetes mellitus, lymphatic leucemia and roentgen sickness following nicotinic acid, sulfapyridine, insulin and well-balanced diet, riboflavin and yeast, respectively. Controls were made, adding cozymase to the same samples of blood, and blood from normal persons was used as an additional control in every instance.

FACTORS WHICH OPERATE TO DISTURB NUTRITIONAL BALANCE AND TO AFFECT THE
COENZYME I AND II CONTENT OF THE TISSUES

External and internal causal factors associated with the development of dietary deficiencies are detrimental to the proper physiologic function of the body. The most frequent cause of nutritional deficiency disease is a decreased intake of vitamins and other nutritious substances. In addition, some persons develop deficiency diseases because of faulty assimilation, even though the dietary intake may be adequate. Particularly in these persons does the continuous excretion of nicotinic acid and other vitamins operate against their general well-being. Excessive exercise taxes their strength and appears to precipitate relapse and clinical manifestations of deficiency disease, whereas acute infection and fever place still greater demand for vitamins upon the body. It appears likely that some of the same influences operate against the

nutritional health of a "normal" person, but beneficial mechanisms act more efficiently and against lesser odds and thus succeed in maintaining the homeostatic equilibrium.

FACTORS WHICH OPERATE TO MAINTAIN NUTRITIONAL BALANCE

Even as there are conditions which upset nutritional equilibrium, there probably are as many factors which function to preserve the physiologic balance. Long before the etiology of pellagra was in any way understood, rest in bed was advocated as the best treatment for the disease. The effectiveness of this treatment is still observed, for a certain percentage of pellagrins in mild relapse, when given rest in bed without specific medication, return temporarily to apparent nutritional balance. Coenzyme I and II studies have been made on such cases, and it was found that the initial concentration of coenzymes I

Fig. 5.—Showing the initial low coenzyme I and II content of the blood of a pellagrins who later showed an increase to normal levels following rest in bed and a caloric maintenance of glucose. This type of observation strikingly illustrates the necessity of considering the patient from a physiologic point of view.

and II per cubic centimeter of blood increased spontaneously along with the clinical improvement that occurred in 30 per cent of the patients who were hospitalized and maintained on glucose and water without specific therapy (Fig. 5). Similar phenomena occurred during the initial treatment of persons in diabetic coma, for no nutrients, other than saline and glucose, were given. Since it was thought that the presence of interfering substances had been ruled out by the addition of standard cozymase solution to blood control tubes, the observations suggested that in these cases there was sufficient storage of nicotinic acid and the coenzymes in various tissues. The observations of other workers seem to support this theory in certain particulars, for the studies of Axelrod and Elvehjem²⁶ and of Kohn, Klein, and Dann²⁷ on dogs with blacktongue, and the unpublished determinations of Axelrod on the cozymase content of skeletal muscle in human beings with pellagra in relapse have shown that the level of these coenzymes, particularly cozymase in the blood, brain, and kidney cortex, remains at a fairly high level in blacktongue, although it decreases in the liver and muscles of dogs with blacktongue and in the muscles of human beings

with pellagra. It seems that there is protective homeostatic control of the storage and distribution of these vital substances in the cells. The process may carry on for the benefit of some organs and at the expense of others, and the equilibration becomes more difficult as the stores of these coenzyme precursors are depleted.

Fig. 6.

Fig. 7.

Figs. 6 and 7.—Variations in content of coenzyme equivalents of red blood cells.

FACTORS CONCERNED WITH THE CONCENTRATION OF COENZYMES IN WHOLE BLOOD AND PACKED CELLS

There has been considerable question as to the most precise method of expressing the units of concentration of these blood coenzymes, principally because of different theories of their formation and function. It has been suggested¹⁵ that the calculation should be based upon the concentration of coenzyme equivalents per eubic centimeter of packed cells since these coenzymes are largely intracellular. Cozyme equivalents, calculated in this manner, appear to compensate for differences in the total volume of red blood cells encountered during any clinical study. It presupposes a constancy of all factors other than the hematocrit values (percentage of cells per volume of blood) and assumes that coenzymes are synthesized and used only in the individual cells in which they are contained. It assumes also that the nicotinic acid amide in tissue fluids and the coenzymes of the cells are in constant equilibrium which is unaffected by changes in the number or size of the cells. Such a consideration would seem to exclude the possibility of any transfer of preformed coenzyme. The presence of these coenzyme-like substances in bacteria-free fresh urine, however, requires some explanation and further investigation of the extracellular existence of these substances. Studies of the excretion of these substances suggest either a diffusion of these coenzymes which may be protected in some way

from destruction by the nucleotidases of the serum, or synthesis and secretion of coenzymes by the cells of the kidney tubules, for normal, freshly voided, sterile urine contains about one to ten times as many coenzyme equivalents as does blood plasma. Little is known about the relative solubilities of the different antipellagric substances, their rates of diffusion, or their selective uptake by different types of cells. The *in vitro* synthesis of the coenzymes in whole blood from nicotinic acid or nicotinic acid amide^{28, 29} shows that some of these substances can enter cells, and it is known³⁰ that coenzyme is taken up from a medium within eight seconds by bacteria which require it for growth. The rate at which nicotinic acid amide or the coenzymes leave cells, however, is not known. The very small quantities of coenzymes in the serum suggest that many factors control the distribution.

An alternate method of expressing the concentration of these coenzymes in the blood is in units per cubic centimeter of whole blood. The reasons for this are several: (1) In anemias of uncomplicated blood loss, coenzyme equivalents per cubic centimeter of whole blood are usually within the normal range, while values per cubic centimeter of cells are usually high. (2) Some pellagrins with anemia have low values for the coenzyme equivalents in whole blood while these values per cubic centimeter of packed cells may be within the normal or high range. In contrast to this, pellagrins with normal hematocrit readings tend to have low values per cubic centimeter of cells as well as per cubic centimeter of whole blood (Table II). (3) There is no evidence that the coenzyme content of the red blood cell is proportional to cell size. It is labile and in most cases seems to be determined chiefly by the concentration of the nicotinic acid in the surrounding fluid, for it has been shown^{15, 16} that the red blood cell can almost double its coenzyme content following the ingestion of nicotinic acid. It appears to us that a calculation using the hematocrit reading as reference is based upon three or more variables: the concentration of coenzymes in the red blood cells, the size of the cells, and the number of red blood cells. These may vary independently and in direct or indirect proportion (Figs. 2, 6, 7).

SUMMARY AND CONCLUSIONS

1. In an extended study of mixed deficiency diseases, it has been observed that the concentration of the substances in whole blood which have the growth-stimulating properties of the pyridine nucleotides for the influenza and parainfluenza bacillus is lower in persons subsisting on deficient diets than in normal persons on optimal diets.

2. Low values for the coenzyme concentration of whole blood have been observed also in diabetes mellitus, leucemia, roentgen sickness, and pneumococcal pneumonia.

3. The concentration of these coenzymes in the blood of malnourished persons was decreased also by exacerbations of the deficiency symptoms, concurrent infections, and fever, or by excessive physical exercise. When these patients improved clinically either after rest in bed, improved dietary intake, or specific medication, a parallel increase in the concentration of these coenzymes in the blood was observed.

4. These studies suggest indirectly that coenzymes I and II in the blood are in homeostatic equilibrium with the acid amide and the same coenzymes in the other tissues of the body.

CLINICAL LABORATORY DETERMINATION OF VITAMIN NUTRITION*

HENRY FIELD, JR., M.D., AND DANIEL MELNICK, PH.D.†
ANN ARBOR, MICH.

IT IS impossible, in a short article, to cover all the phases of clinical laboratory determination of vitamin nutrition, to give anything approaching a complete bibliography of the subject, or to discuss in detail controversial matters. With the introduction of simple methods for analysis of ascorbic acid, clinical laboratory diagnosis of vitamin nutrition began to be possible and its importance is increasingly recognized. Scurvy was formerly considered a rare disease. It has been surprising to find how many people have blood levels of ascorbic acid in or near the range at which clinical scurvy occurs. Likewise, when attention is paid to the symptoms which have been known to occur in classical pellagra and to the lesser objective manifestations of it, the number of patients whose symptoms may be alleviated by the administration of nicotinic acid or the vitamin B complex has been remarkable.¹

Our position in respect to vitamin deficiencies is now much the same as that of clinicians in respect to thyroid disease before clinical observations could be checked by basal metabolic rate determinations. The more extreme deficiencies usually can be recognized, but for each one of these there are, presumably, many cases of less apparent deficiency disease causing ill health.

The development of means of laboratory diagnosis of deficiency for many vitamins does not now appear to be as simple a problem as it has been for vitamin C. It may be expected, however, that means will be found. Then many cases of ill health of obscure cause may be explained. Many patients who are now commonly called psychoneurotics may receive a different diagnosis and more appropriate treatment. The lesser symptoms of deficiency disease may become familiar enough so that patients may commonly be given appropriate supplements without laboratory tests. More will be learned of the effects of vitamin deficiency on body function, such as the parallelism between the ascorbic acid and the complement activity of the blood observed by Ecker and Pillemer² in two scorbutic patients during treatment. The levels of vitamin nutrition beyond which further improvement will not benefit the individual may be determined.

Chemical and biologic methods have been developed for the assay of certain vitamins in the body fluids. The first chemical method was based upon the blue color which develops when vitamin A reacts with antimony trichloride in chloroform solution, observed by Carr and Price³ in 1926. This was first used for the determination of vitamin A in fish oils. The earlier analyses of vitamin A in blood serum were unreliable because of inadequate methods of extraction and separation from interfering substances. Von Eckelen and Emmerie⁴ in 1935

*From the Department of Internal Medicine, University of Michigan, Ann Arbor.

†Upjohn Fellow in Clinical Research.

introduced the important step of heating serum with potassium hydroxide before extracting it. This was used in the extensive studies of Lindqvist.⁵ Dann and Evelyn⁶ in 1938 used the Evelyn photoelectric colorimeter to permit reading of the blue color at its maximum and thereby avoid errors due to the waxing and waning of the color. Kimble⁷ described procedures to permit the use of this determination on small amounts of serum.

Ascorbic acid was the next vitamin to be measured by chemical analysis. Zilva in 1927⁸ reported that there was in fresh fruit juices a substance that would reduce phenolindophenol which was closely associated with the vitamin but was not, he thought, identical with it. Tillmans⁹ was able to eliminate the apparent discrepancies which Zilva had reported and established that vitamin C was a reducing substance. On the basis of extensive studies on oxidation-reduction potentials of dyes by Clark, Gibbs and associates¹⁰ he chose to use 2, 6-dichlorophenolindophenol which has continued to be used. Other chemicals have been used for titration but have not found much favor.

Because other constituents of body fluids are also reducing substances, the reaction is not specific for ascorbic acid. In blood other reducing substances are present in small amounts and cause reduction slowly. Consequently, by proper speed and choice of end point satisfactory results may be obtained with blood by the titration methods of Farmer and Abt,¹¹ and Pijoan and Klemperer,¹² which have been used extensively in this country.* In urine, however, Evelyn, Malloy, and Rosen,¹⁴ and Roe and Hall¹⁵ report that a large part of the reducing capacity is due to substances other than ascorbic acid. Previous studies of urinary ascorbic acid by titration methods, accordingly, need re-evaluation.

Mindlin and Butler¹³ described a method using the photoelectric colorimeter which eliminates the error due to other reducing substances. Using a larger quantity of dye than will be reduced, the residual color is read at thirty seconds. Correction for other reducing substances may be made by extrapolation to zero time from subsequent readings. Bessey¹⁶ added the further step of dropping in a crystal of ascorbic acid after the determination to complete the reduction of the dye and obtain a subsequent blank.

The status of chemical methods for vitamin B₁ determination is less completely established. The thiochrome reaction, which permits measurement of the fluorescence of partially oxidized thiamin, first observed by Peters,¹⁷ studied further by Jansen,¹⁸ and applied to the analysis of urine by Westenbrink and Goudsmit¹⁹ is capable of detecting small amounts of thiamin. With it there are possibilities of error which we have pointed out²⁰ and which are evidenced by the variety of procedures used in the attempt to avoid them and the wide variation in the range of values obtained by the different methods. The thiochrome method will be an asset to the clinical laboratory if reasonably accurate results may be obtained without too time-consuming procedure.

We have worked out a method^{20, 21} based on the reaction of thiamin with p-aminoacetophenone reported by Prebluda and McCollum²² which is highly specific and accurate. With urine, the necessity of concentration of the vitamins into a small volume and its separation from substances which inter-

*See Table I of Mindlin and Butler.¹³

fere with the reaction makes the test time-consuming. Hence the method is suited to the research laboratory and for the routine analysis of materials with a high content of the vitamin.

Meicklejohn²³ used its growth-promoting effect on *Phycomyces blakesleeanus* to measure thiamin in blood. Sinclair²⁴ has shown that the increment of growth is not specific for thiamin and has proposed to neutralize the influence of other substances by the addition of whole blood to the medium. Goodhart and Sinclair²⁵ have also measured by a fermentation method cocarboxylase in blood, where it comprises the major fraction of thiamin.

Before analyses of vitamins in the body fluids are clinically useful, it must be shown that the figures obtained reflect the level of vitamin nutrition in the tissues. In the case of ascorbic acid, blood values apparently do this. Van Eckelen²⁶ reported a straight line relationship between blood levels and the doses required for saturation. This deserves further investigation, but a correlation between intake and blood levels of ascorbic acid has been observed repeatedly.

We²⁷ have observed a close correlation between dietary history and urinary excretion of thiamin. Our studies²⁸ on experimental thiamin deficiency indicate that urinary excretion falls off very promptly when an inadequate diet is taken, and that the excretory response to a test dose is then needed to evaluate the body stores. On the other hand, when a person who has been depleted is given a normal intake of thiamin, the depleted state of the body stores continues to be shown by a low urinary excretion for a long time. In a large number of determinations of the blood cocarboxylase in a large variety of conditions Goodhart and Sinclair²⁹ obtained deviations from normal in the expected directions. The wide range of values which they found in the same normal individuals at different times indicates the necessity of taking blood samples at a constant, longer time after meals or a large possibility of error in the method.

Relatively little study has been made of riboflavin in human body fluids. Sebrell³⁰ and Sydenstricker³¹ and their associates have recently described manifestations of riboflavin deficiency which we now find to be fairly common. Ferrebee³² has recently described methods for measuring riboflavin in urine, in which the optical system is a considerable improvement over that of previous methods and for which the reported comparative results indicate good specificity and accuracy. The findings of an early drop in urinary excretion of riboflavin during experimental deficiency in rats reported by Vivanco³³ and in human beings by Emmerie,³⁴ together with the subsequent response to test doses reported by the latter, indicate a relation of urinary excretion to riboflavin nutrition similar to that which we have found for thiamin.^{27, 28}

In the case of nicotinic acid, there is no close correlation between the content of body fluids and that of tissues. Both Kohn³⁵ and Elvehjem³⁶ and their co-workers, using biologic methods of assay, have reported that the nicotinic acid-containing enzymes in the blood are not significantly diminished in experimental black tongue or in human pellagra, although the tissues are depleted. Using our chemical method³⁷ and trying various methods of "saturation" tests, we³⁸ have not found much promise for the direct laboratory diagnosis of nicotinic acid deficiency.

The significance of blood analyses of vitamin A remains to be determined. Wide variations in apparently normal people have been found by Lindqvist.⁵ McCoord and Luce-Clausen³⁹ have found no significant increase in the blood content of rats fed supplements of vitamin A, although the content of their livers was greatly increased over the controls. Lindqvist⁵ found no significant change in the blood values of human beings fed large supplements of vitamin A.

Vitamin A is insoluble in water. Josephs⁴⁰ has reported a rough correlation between the vitamin A and cholesterol and total lipids in the blood in persons whose nutritional status was not evaluated. This had been previously a subject of interest. Lindqvist⁴¹ reported that during convalescence from pneumonia serum vitamin A values rose before there was any change in blood cholesterol. It might be expected that there should be a closer correlation of the vitamin A of the serum with its neutral fats than with its lipids.

Another approach to the clinical laboratory diagnosis of vitamin deficiency is the measurement of resultant disturbances of body function. When the specificity for a vitamin deficiency of the disturbance of body function and its sensitivity are established, such a method may help to establish a normal level of vitamin nutrition. The question of specificity and sensitivity makes most of such methods of doubtful value.

Attempts have been made to diagnose vitamin C deficiency by measurement of capillary fragility. As in other studies, without chemical control, Abt, Farmer, and Epstein⁴² did not find any uniform relation between capillary fragility and blood ascorbic acid or dietary history. Considering the number of factors concerned in purpura and its inconstancy in scurvy, this is not surprising.

Pyruvic acid in blood and urine has been studied in relation to thiamin nutrition. Embden and associates⁴³ showed that pyruvic acid is a normal intermediary in the carbohydrate metabolism of muscle. Peters and Sinclair⁴⁴ identified pyruvic acid in lactate solutions in which avitaminose pigeon brain had been incubated. Thompson and Johnson⁴⁵ demonstrated an increase of pyruvic acid in the blood of avitaminose pigeons. Platt and Lu⁴⁶ have shown increases of pyruvic acid in the blood of all cases of fulminating beriberi but in only a portion of their subacute cases. They have proposed⁴⁷ the determination of the increase of blood pyruvate after exercise as a test for thiamin deficiency, but their reported results were inconsistent. They did not report the amount of exercise used and their test perhaps deserves further investigation.

Attempts have been made to replace the tedious hydrazone method of blood pyruvate analysis by determination of bisulfite-binding substances (B.B.S.) in the blood. Bisulfite-binding substances include other carbonyl compounds. While in experimental animals the blood bisulfite-binding substances have been found to be well correlated with thiamin deficiency, in man such correlation has been found neither with clinical evidence of thiamin deficiency⁴⁸ nor with our determinations of urinary thiamin.⁴⁹ Bauerji and Harris⁵⁰ have shown that the addition of sodium lactate to the diet caused increased excretion of bisulfite-binding substances in the urine of rats with vary-

ing grades of thiamin deficiency. They proposed a similar procedure for testing human beings, but stated that preliminary tests indicated that it may be necessary to modify the procedure in some details.

Night blindness has been known since the days of Hippocrates when one of the methods of its treatment was a liver diet. Block in 1921⁵¹ suggested that it was due to vitamin A deficiency. Fridericia and Holm⁵² showed that in experimental animals the concentration of visual purple in the retina was dependent upon vitamin A in the diet and that without it they became night blind.

Attempts to apply determination of dark adaptation to the evaluation of vitamin A nutrition have resulted in most conflicting reports. It seems probable that these discrepancies are due to varying techniques which may not adequately control the biochemical factors involved, and possibly to the influence of other vitamins upon dark adaptation. Harris and Abbasy⁵³ point out that most of the failures to correlate dark adaptation with vitamin A nutrition have been by those using the biophotometer. Possible inadequacies of the procedure used with this apparatus have been discussed by them, by Hecht and Mandelbaum,⁵⁴ and by Thomson and co-workers.⁵⁵ The extensive study of dark adaptation by Hecht⁵⁶ furnishes a basis for clinical application. Thomson and co-workers^{55a} reported that ten minutes of preliminary dark adaptation, followed by four minutes of bleaching with a bright light, was not adequate to eliminate the effect of previous light. Even twenty minutes of dark adaptation was not adequate for some subjects.^{55b} Harris and Abbasy⁵³ considered the bleaching light of the biophotometer too weak. Hecht⁵⁶ has shown the difference in the dark adaptation of cones and rods and the desirability of testing a known segment of the retina because of the different distribution of cones and rods. It will always be necessary to have calibrated accurately the intensity of the measuring light, and to eliminate the influence of unrelated ocular conditions. Nevertheless, the results which we have seen obtained by Curtis and his associates⁵⁷ indicate that useful studies can be done with the biophotometer—perhaps because these studies were on in-patients protected from strong light.

The suggestion of Hecht and Mandelbaum⁵⁴ that the slow recovery of dark adaptation in their patients receiving large supplements of vitamin A, compared with the very rapid recovery of dark adaptation in the patients of Wald, Jeghers, and Arminio⁵⁸ and others, was due to their failure to add supplements of other vitamins to their experimental diet is probably correct. The retinas of many species of animals have been found by von Euler and Adler⁵⁹ and others to contain relatively high concentrations of riboflavin which has been supposed to be concerned with dim vision. Sydenstricker and his associates⁶¹ reported that dimness of vision is a common symptom of riboflavin deficiency in human beings. Kimble and Gordon⁶⁰ reported that individuals who had failed to improve their dark adaptation with supplements of vitamin A were promptly restored when riboflavin was also added. In some others who failed to improve with riboflavin, ascorbic acid supplements were followed by satisfactory improvement. It is possible that some of the discrepancies in the reports concerning the relation of vitamin A and dark adaptation are due to failure to eliminate the influence of other vitamins.

The relation of abnormal pigments in urine to pellagra will become of especial importance if a method for direct determination of nicotinic acid nutrition is not devised. Beekh, Ellinger, and Spies⁶¹ reported the occurrence in the urine of pellagrins of large amounts of porphyrins. Later Spies and his associates⁶² called the pigment "porphyrin-like substances." They reported⁶³ that the pigment excretion returned to normal in from one to six days in 16 pellagrins receiving vitamin supplements. But in 4 pellagrins on a basal diet without supplements, the pigment excretion also returned to normal, although only after four to six weeks. Watson⁶⁴ and Meiklejohn and Kark⁶⁵ have identified the abnormal urinary pigment as uroscopin and probably another related pigment. They report the occurrence of these pigments in the urine of patients with diseases other than pellagra. The possibility of an associated vitamin deficiency in such patients and the relation of such pigment excretion to liver diseases requires further investigation.

THE ROLE OF BLOOD CLOTTING ANOMALIES IN THE HEMORRHAGIC DISEASES

JOHN H. FERGUSON, M.D., ANN ARBOR, MICH.

BLEEDING involves factors of positive causation as well as of failure to control. Causes include injuries and factors relating to capillary fragility. The latter is increased in scurvy and in capillary and thrombocytopenic purpuras. It has not been convincingly proved that the citrus juice factor which appears to control capillary resistance is the vitamin P of Szent-Györgyi and his colleagues,¹ vitamin C, or an unidentified agent. Vitamin C is ascorbic (cevitamic) acid,² whereas vitamin P or citrin consists of flavone-glucosides.³

Arrest of hemorrhage and plugging of the vascular leak involve vasoconstriction and thrombus formation. These are illustrated in some published experiments³ on frog mesenteric capillaries. Fig. 1* shows an endothelial cell selectively stimulated by micromanipulation. The ensuing contraction partially occludes the lumen of the capillary. As shown in Fig. 2,[†] a more vigorous pricking of the endothelium has caused injury to the vessel wall, but the escape of blood is prevented by the formation of a thrombus consisting, at first, solely of cells. If the blood flow is sufficiently slow, the red blood cells take part and, in the example cited, they form the whole mass, except for a single white cell (IV) seen clinging to the distal end of the clump. With a faster blood flow only the "stickiest" cells adhere and agglutinate. In the mammal these are the platelets, some of which are shown in the blood clot in Fig. 3. Note the little vesicles visible under the dark-field illumination. These represent the result of a peculiar form of lysis which occurs in platelets just prior to blood coagulation.⁴ The altered platelets provide some agent which takes part in blood coagulation, and a network of fibrin threads (a few of which are seen in Fig. 3) binds the cell thrombus more firmly together. The point to be emphasized, however, is that the special function of platelets and other cells in thrombus formation is to adhere together and add mechanical strength and tenacity to the clot. Platelets are believed also to aid in the clot retraction which makes for additional firmness. We shall make further reference to their role in blood coagulation.

The following deals principally with the clotting mechanism proper in an attempt to show how our current knowledge,⁵ largely derived from *in vitro* experiments, helps to rationalize many of the clinical problems of the so-called "hemorrhagic diathesis" or "bleeding tendency."

Fig. 4 presents a scheme of the essential clotting reactions. The main phenomena are well understood: a coagulant (thrombin) is first formed from an

*Reference 3, Fig. 2, p. 463.

†Reference 3, Fig. 4, p. 464.

inactive precursor (prothrombin) and then acts on fibrinogen to form fibrin. Prothrombin and fibrinogen are prepared by empirical methods from the globulin fraction of the plasma proteins. The conversion of prothrombin to thrombin requires certain activating agents. The first is ionized calcium salts.⁶ The second is the so-called thromboplastic factor which has come into new prominence in the last few years. The phospholipid cephalin has an important role, but there are undoubtedly other accessory factors (*vide infra*). The clotting reactions may be inhibited by specific agents, acting either upon the process of prothrombin activation (whence the designation "antiprothrombic") or upon

Fig. 1.—Untouched photomicrograph, showing localized contraction of single endothelial cell (E) of frog's mesenteric capillary, in response to micromanipulation by needle (N). The appearance prior to stimulation was very similar to that of an endothelial cell (en.). A previously manipulated Rouget cell (R) may be drawn slightly from the capillary wall without affecting the underlying blood vessel. There is "physiologic flow," unrelated to the manipulative procedures.

Fig. 2.—Untouched photomicrograph (frog mesentery), showing (1) maximal capillary dilation and rapid blood flow due to ineipient inflammatory reaction; (2) formation of red blood cell "thrombus" (T) at site of endothelial injury, effected by microdissection needle [a single white corpuscle (W) is attached to lower pole of thrombus]; (3) the constricting effect of connective tissue bands (B); (4) a marginating leucocyte (M); and another (E) emigrating through the wall of capillary (C).

the thrombin-fibrinogen interaction (hence the term "antithrombic"). The fundamental reactions are subject to a variety of nonspecific influences, such as temperature, pH, salt concentration, "wetting" (lowering of surface tension), dilution, and the like.

Fig. 3.—Dark-field photomicrograph of coagulated human blood drop. Note especially the vesicular formations from altered platelets and the "needles" of fibrin. The field also includes numerous refractile erythrocytes and a single polymorphonuclear (neutrophilic) leucocyte.

Fig. 4.—*Activators: (1) Calcium salts. (2) Thromboplastic agents, including (a) phospholipids (cephalin), (b) ? thromboplastic enzyme, and (c) ? diffusible factor.

**Inhibitors: Antiprothrombins, including heparin and other sulfonic substances.

***Inhibitors: Antithrombins, including hirudin, heparin plus plasma-albumin, etc.

Nonspecific factors: Temperature, pH, salt concentration, "wetting," etc.

Fig. 5 shows the chief steps in a typical experiment to analyze the clotting mechanism by purifying its components with modern methods.⁷ The diagram illustrates the clotting time on recalcifying (with and without added cephalin) the various fibrinogen-containing materials. Each interval represents one minute. An especially careful technique in collection of the blood, repeated centrifugalization, and Berkefeld filtration of the plasma insure a plasma quite free from any products of tissue, platelet, or other cellular (including bacterial) origin. Such plasma invariably clots in about ten minutes or less on simple recalcification (No. 4). This is a minor delay over the two to four minutes for unfiltered plasma, but the clotting time is easily restored to normal by adding a trace of pure cephalin (No. 5). The important conclusion is that the blood plasma itself contains all the essential factors for clotting, including much more phospholipid than the whole of the platelet content. Of course, maintenance of the normal fluidity of blood must mean that these factors are not all "avail-

able." It is quite possible that the thromboplastic factor in the platelets is more readily available than that of the plasma, but we are inclined to minimize the role of platelets and similar material in blood clotting. Hence, we do not attribute the bleeding in cases of thrombocytopenia to any significant clotting anomaly, but refer to other explanations, including (1) decreased capillary resistance to injury, and (2) poor thrombus formation in terms of mechanical properties, such as adhesiveness and retractibility. These have already been discussed. Clotting time is normal in thrombocytopenic purpura; it is only the bleeding time which is prolonged.

CLOTTING PROPERTIES OF REAGENTS PREPARED FROM DOG BLOOD

Protocol. Temperature : 38°C. pH : 7.5

Fig. 5.

Returning to the fibrinogen, it is seen that the final preparations (Nos. 8, 9) show no clot on recalcification even with the addition of cephalin or other thromboplastic agents. This means that we have eliminated all traces of prothrombin. Clotting occurs, however, in less than one minute on the addition of an active thrombin preparation. We have recently succeeded in obtaining fibrinogen in the dry state by means of the lyophilic technique.⁸

Fibrinogen, of course, is the sine qua non of the fibrin clot. It is found that the fibrinogen concentration in experimental tests may be varied widely with only a minor influence on coagulation time. The character of the clot alters. Below a certain concentration, the coagulum formed is very weak,

suggesting that the equivalent *in vivo* would not be much good for the arrest of hemorrhage. There are marked variations in the blood fibrinogen content in various diseases, and hemorrhagic conditions associated with lowering of the plasma fibrinogen are clearly recognized although they appear to be rare. Pseudohemophilia is said to fall into this class. The typical case is familial and has a long bleeding time, but a normal platelet count.⁹ A simple plasma protein analysis would establish the fibrinogen deficiency but, as far as we are aware, this has seldom been reported in the clinical literature. In the fibrinogen deficiencies accompanying liver dysfunction, the prothrombin is usually lowered as well and this often precedes the fibrinogen decrease. Naturally, one would not expect to benefit these patients with any measures aimed solely at increasing the thrombic function. The rational treatment is to tide over the hemorrhagic crisis with transfusions and subsequently to build up the blood proteins by dietary and other means.

RATE OF THROMBIN FORMATION: PROTHROMBIN (10) + $\frac{N}{10}$ CaCl₂ (1)
+ 0.1% CEPHALIN (1). DOG. 38°C.

Fig. 6.—Prothrombin activation curve. This affords information as to the rate and amount of thrombin formation. The role of calcium is evident from the different effects of oxalate (or citrate) at the three zones depicted. In Zone I thrombin formation is completely inhibited; in Zone II the oxalate progressively removes calcium and inactivates the "intermediary" complex; in Zone III the "ripe" thrombin resists the decalcifying action of oxalate, etc.

Most of our recent work concerns the process of conversion of prothrombin to thrombin. We have little to say as to the nature of prothrombin. It is obtained from plasma by various precipitation methods.⁷ The best preparations contain proteins, phospholipids, salts, etc. However, it is significant that the agents necessary to activate prothrombin are being more and more clearly defined. Prothrombin, in our experience, is never activated spontaneously. It needs calcium salts and usually some thromboplastic agent in addition. In the last two experiments of Fig. 5, the prothrombin and fibrinogen solutions were

extracted with benzene prior to the tests.¹⁷ The emphasis is on the result rather than the interpretation of the technique. Experiment No. 11 shows that the benzene-extracted fibrinogen is readily clotted by a thrombin made from the benzene-extracted prothrombin by five minutes' incubation with calcium and cephalin. Experiment No. 12 shows that calcium alone is insufficient. We shall return to this point later.

Fig. 6 illustrates the standard technique with which we follow the process of thrombin formation. A mixture of prothrombin and calcium salt plus any activator or inhibitor we wish to investigate is incubated, preferably at a cool temperature (10 to 20° C.), in order to control possible deterioration.⁷ At various time intervals, charted on the abscissa of the graph, a measured sample is removed and added to a fixed amount of fibrinogen (under constant conditions), and the clotting time is noted and plotted on the ordinate of the graph. Clotting time is a measure of thrombin concentration and gives us a relative value for the amount of thrombin present at the time the test is made. The shorter the clotting time, or the lower the curve, the more potent is the thrombin. We may term the graph the "activation curve" of the particular thrombin mixture. We have published¹⁰ a series of such curves with varying amounts of cephalin. The more phospholipid, the lower the curve, i.e., the greater the thrombin formation. The same sort of thing occurs, but even more strikingly, when we vary the calcium.¹⁰

TABLE I
SCHEMA OF THROMBIN FORMATION

Plasma globulins (excluding fibrinogen) or agent associated with proteins	1. Plasma lipoproteins 2. Platelets 3. Other cells and tissues	Blood calcium	
Prothrombin (? protein)	"Available" cephalin (phospholipid)	Calcium salts (ionized)	Zone I
	Intermediary complex (protein-phospholipid-calcium)		Zone II
	"Ripe" thrombin		Zone III

Table I summarizes our view as to the fundamental reactions of thrombin formation. Evidence previously published¹¹ supports the view that there is the formation of an intermediary colloidal complex containing prothrombin, cephalin, and calcium in definite quantitative proportions. The final, older ("ripe") thrombin may be prepared free from all traces of calcium; it retains considerable activity after alcohol-ether (3:1) extraction (at room temperature) and is well preserved under acetone.

It is only the ionized form of calcium which takes part in the conversion of prothrombin to thrombin.¹² Ransmeier and McLean¹³ have recently found the optimum calcium ion concentration for plasma clotting to be almost identical with the normal value for "diffusible" calcium in serum. Too much calcium

is inhibitory, a nonspecific salt (cation) effect.¹⁴ Too little fails to convert all the prothrombin. The minimum calcium ion concentration for clotting is below the lowest serum calcium level compatible with life, at least in experimental dogs. It would seem unlikely that clinical variations in the serum calcium level can materially affect clotting time or that calcium administration can be expected to exert any therapeutic benefit attributable to assistance in the clotting mechanism.

Typical prothrombin preparations are very poorly activated by calcium alone, and some solutions (Fig. 5) are quite unable to clot fibrinogen on simple recalcification. In this case a so-called "thromboplastic agent" is an essential addition. The phospholipid cephalin, as isolated from brain and other tissue sources, is such a thromboplastic agent. Crude aqueous tissue extracts, known as thrombokinas or thromboplastins, act similarly,¹⁵ but we shall later point out some significant differences. Pure cephalin is surprisingly active, a solution as great as 1:1,000,000 exerting a definite thromboplastic effect. Some snake venoms are more than one hundred times more active than this.¹⁶ We have analyzed blood plasma, platelets, and corpuscles from the various hemorrhagic diseases without finding any significant decrease in total phospholipid or cephalin content.¹⁷

Prothrombin solutions, which were very poorly activated by calcium alone, analyzed some 8 to 30 mg. per cent of total phospholipid, of which about 40 to 60 per cent was cephalin (choline-free). These amounts of cephalin, added in the form of a solution of the isolated phospholipid, produce rapid and abundant thrombin formation. There is an experimental difference, therefore, between cephalin in simple solution and the form in which it occurs in the natural materials. We now have clear evidence¹⁷ that the cephalin in practically every crude material studied (and this applies to plasma, prothrombin, platelets, lung and brain extracts) is all in firm combination with the proteins present. This is true, at least, of the ability to extract it with simple fat solvents, such as ether, benzene, and the like. With regard to the crude thromboplastins (or aqueous tissue extracts), it has become evident in contemporary methods of prothrombin estimation¹⁹ that these materials are much more active than the equivalent of their isolated phospholipids. Our quantitative data prove this beyond a reasonable doubt. We are thus led to two conclusions, viz., (1) that the phospholipid of the natural thromboplastic system is not necessarily "available" for clotting, and (2) that a new factor must be sought for to explain the full mechanism of thromboplastic action. The latter conclusion is foreshadowed in the investigations of plasma or serum globulin in hemophilia by Bendien and van Creveld,²⁰ of Amsterdam, and also by a group of Harvard workers.²¹ Howell, of Baltimore, has reported preliminary attempts at isolation, but his published data²² neither suggest the possibility of an enzyme nor do they suffice to rule it out. In deference to these and other claims,²³ we have included a possible diffusible factor among accessory thromboplastic agents (Fig. 4).

An extensive series of comparative experiments with Kunitz and Northrop's crystalline trypsin leads us to believe that such an enzyme may be the

thromboplastic factor for which we are looking. The published data¹⁷ may be condensed into the statement that an artificial system of trypsin plus calcium closely resembles aqueous tissue extracts in every reaction tested. Cephalin is also adjuvant, and, in such experimental differences between cephalin and crude thromboplastin as can be defined, the new mixture provides a means of bridging the divergence of findings. The accessory thromboplastic action of crystalline trypsin is evident in the thrombin formation data of Table II.

TABLE II

THE ROLE OF CALCIUM, CEPHALIN, AND CRYSTALLINE TRYPSIN IN EXPERIMENTAL THROMBIN FORMATION

Thrombic mixtures (T) = 4.0 c.c. prothrombin solution + 1.0 c.c. activating agents (suitably diluted). Calcium is expressed in milliequivalents, and trypsin and cephalin in milligrams, per 5.0 c.c. of thrombic mixture. Thrombin formation at 15° C. Clotting times for 0.5 c.c. T + 1.0 c.c. fibrinogen solution (prothrombin-free) at 38° C.

T	ACTIVATING AGENTS IN THROMBIC MIXTURE	THROMBIN INCUBATION PERIOD (MINUTES) AT 15° C.							
		2'	5'	10'	20'	30'	45'	60'	180'
1	Calcium (0.025)		203"	167"	55"	28"	19"	13"	47"
2	Calcium (0.025) + cephalin (0.25)		47"	35"	25"	22"	19"	18"	18"
3	Calcium (0.025) + cephalin (0.25) + trypsin (0.05)	40"	27"	20"	20"	20"		20"	
4	Calcium (0.025) + trypsin (0.05)		180"	145"	25"	20"		20"	
5	Trypsin (0.05)				120"	40"		25"	

Tryptic activity in blood plasma and tissue extracts has been previously established and is a complex story, involving an inactive enzyme precursor which must be freed from a specific inhibitor and then activated by a special Kiasase.²⁴ We are currently engaged in the task which has been opened up for correlating all this with blood coagulation. In the meantime, it can be stated that the ability of both trypsin and tissue extracts to restore the coagulability of hemophilic blood *in vitro* is due to the acceleration of the conversion of prothrombin to thrombin, delay in which has long been recognized to underlie the coagulation defect of hemophilia.¹⁸ This is shown for trypsin in Table III;⁶ tissue extracts are similar; cephalin has little or no influence. There does not seem to be anything wrong with the tissue factor in hemophilia, which probably accounts for the normal bleeding time which is usually obtained by the Duke test in which, of course, the blood flows over the tissues damaged by the puncture needle. There is an unusually slow breakdown of platelets in hemophilia,⁵ but it is difficult to say whether this is the cause or the effect of the plasma deficiency. Our suggestion is that hemophilia is a deficiency in the plasma content of the new thromboplastic factor, which we are tentatively calling "thromboplastic enzyme." We have reason to believe that the enzyme normally acts by "mobilizing" calcium and cephalin for the conversion of prothrombin to thrombin.¹⁷

Prothrombin is the protein component of the clotting agent. We are not prepared to discuss the hypothesis advanced by Eagle,²⁵ which suggests that it assumes an enzyme-character after conversion to thrombin, but we would like to review current methods of prothrombin estimation and the role of vitamin

*Reference 18, Table II.

K in the treatment of prothrombin deficiencies. Clotting time in fibrinogen-thrombin mixtures is a linear function of the thrombin concentration. If, therefore, adequate calcium and thromboplastin are added to convert all prothrombin to stable thrombin, it is possible to obtain a measure of prothrombin concentration in plasma, etc., in terms of an empirical standard control.

TABLE III

ACTIVATION OF RECALCIFIED HEMOPHILIC "GLOBULIN SUBSTANCE" (PROTHROMBIN) BY CRYSTALLINE TRYPSIN

G_1 = 2.0 c.c. hemophilic "globulin substance" (G) + 0.4 c.c. distilled water + 1.6 c.c. N/10 CaCl_2 .

G_2 = 2.0 c.c. hemophilic "globulin substance" (G) + 0.4 c.c. (= 0.1 mg.) trypsin + 1.6 c.c. N/10 CaCl_2 .

Mixtures held at 24° C.; 0.25 c.c. test portions added to 0.5 c.c. quantities of hemophilic citrated plasma (same case) at times shown. Clotting times, seconds, at 38° C.

	THROMBIN FORMATION PERIOD, MINUTES, AT 24° C.					
	1'	5'	10'	20'	30'	45'
G_1	270"	180"	145"	135"	105"	62"
G_2	40"	17"	10"	7"	7"	7"

Controls.—1. 0.5 c.c. hemophilic plasma + 0.3 c.c. distilled water + 0.2 c.c. N/10 CaCl_2 = 720" (C.T.)

2. 0.5 c.c. hemophilic plasma + 0.1 c.c. H_2O + 0.2 c.c. "G" + 0.2 c.c. N/10 CaCl_2 = 275"

3. 0.5 c.c. hemophilic plasma + 0.3 c.c. H_2O + 0.2 c.c. (= 0.1 mg.) trypsin = no clot

4. 0.5 c.c. hemophilic plasma + 0.2 c.c. "G" + 0.2 c.c. CaCl_2 + 0.2 c.c. trypsin = 70"

There are many technical difficulties, the least controlled being the possibility of prothrombin deterioration. Quick's test²⁶ is a relatively simple attempt, consisting of oxalated plasma plus calcium plus brain thromboplastin, the clotting time of which is compared under standardized conditions with a normal control (or series). However, the test is really timing two independent reactions, viz., the conversion of prothrombin to thrombin on the one hand, and the actual fibrinogen-thrombin interaction on the other.²⁷ This is an important theoretical objection but may not be unduly significant for clinical interpretations. Smith and his colleagues²⁸ at Iowa have a more complicated technique which endeavors to separate the two phases of clotting. Without entering into a technical discussion, it may be stated, for the consideration of those who feel critically towards the new prothrombin tests, that they are still in a highly empirical stage. There is a tendency to avoid arbitrary "percentages" of prothrombin and to be satisfied with a comparison of the actual clotting times of the unknown and normal controls. As rough indices of plasma prothrombin content, these tests do give valuable information and there can be no doubt that prothrombin deficiency is an important factor in certain hemorrhagic conditions, such as vitamin K deficiency in chicks, certain toxic states in domestic animals, experimental and clinical disorders of the liver and biliary system, and, of special interest to pediatricians, hemorrhagic disease of the newborn.²⁹ All these are benefited by vitamin K preparations. This fat-soluble dietary factor³⁰ discovered by Dam (Copenhagen) and by Almquist (California) has now been shown to be a common property of a number of 1, 4-naphthoquinones, and we may shortly expect commercial exploitation of active synthetic products, as well as the natural concentrates of alfalfa, kale, spinach, tomatoes, dried

carrot tops, chestnut leaves, oak sprouts, soybean oil, putrefied fish meal, etc. Naphthoquinones are associated with bacterial pigment metabolism (as in the phthiocol from the tubercle bacillus). Alimentary tract microorganisms are thought to elaborate adequate vitamin K in most animals, with the possible exception of very young human infants. Bile is probably necessary for absorption of the vitamin. Dr. A. M. Snell³⁷ and his colleagues (Mayo Clinic) emphasize the importance of intestinal conditions in vitamin K absorption, and it must also be stressed that the effectiveness of therapeutic use is dependent upon an adequate liver function. Use in the hemorrhagic diseases is indicated in, and should be confined to, cases with prothrombin deficiency.

TABLE IV

EFFECTS OF HEPARIN ON THE FORMATION OF THROMBIN FROM RECALCIFIED PROTHROMBIN IN THE PRESENCE OF VARIOUS THROMBOPLASTIC AGENTS

Thrombic mixture (T) = 4 c.c. prothrombin solution + 1 c.c. activator (s) plus inhibitor (suitably diluted), incubated at 15° C. All mixtures include CaCl₂ (0.05 meq. Ca per 5 c.c. T). Cephalin, trypsin, and heparin : mg. per 5 c.c. T. Clotting Times (sec.) at 38° C. : 1 c.c. fibrinogen (prothrombin-free) + 0.5 c.c. T.

T	THROMBOPLASTIC AGENT	INHIBITOR	THROMBIN FORMATION PERIOD, MINUTES, AT 15° C.					
			1'	3'	10'	20'	30'	60'
1	*Cephalin (0.1)	—	—	50"	20"	11"	9"	9"
2	Cephalin (0.1)	Heparin (0.5)	—	∞	∞	∞	∞	∞
3	†Brain P-lipids (0.025)	—	50"	20"	10"	8"	6"	6"
4	Brain P-lipids (0.025)	Heparin (0.5)	∞	∞	∞	∞	1800"	360"

9	Trypsin (0.05)	—	∞	95"	30"	15"	14"	11"
10	Trypsin (0.05)	Heparin (0.5)	∞	∞	660"	70"	32"	18"

*The cephalin was an old preparation which appears to have lost somewhat more than three-fourths of its original potency.

†Quick's "thromboplastin" extracted with alcohol-ether (3:1); acetone-insoluble P-lipids recovered in ether-petroleum ether, dried, and prepared in aqueous solution (1:10,000).

‡Indicates incomplete coagulation.

Bleeding in allergic states is no doubt a greater problem than can be explained in the light of enrrtent knowledge, but the following experiment from the Toronto laboratories³¹ appears to be of considerable significance. Dogs were thrown into anaphylactic shock after sensitization to alum-treated horse serum. During shock the blood became incoagulable and this was shown to be associated with a great outpouring of heparin. It could be demonstrated in the blood in several ways, including the actual isolation of the barium salt in crystalline form.³⁷ Heparin³² is a product originally isolated from the liver by Howell and Holt³³ in 1918, but now prepared from lung³⁴ in the Connaught laboratories at Toronto. It results from the combination of several organic acids, including mucicoin-polysulfuric acids, with the base glucosamine (Jorpes).³⁵

If the anaphylactic experiment is repeated after extirpation of the liver in an acute experiment, the dog still shows symptoms of shock, but the blood

is no longer incoagulable and there is no demonstrable heparin increase. It may be concluded, therefore, that in cases with demonstrable increase in the antithrombic factors in the blood, bleeding may be associated with the outpouring of heparin from liver reserves.

TABLE V

SYNERGISM BETWEEN ANTITHROMBIC ACTIONS OF HEPARIN (CONNAUGHT LABORATORIES) AND CRUDE PLASMA "ALBUMIN" (DIALYZED)

Thrombin: Stock preparation (prothrombin + calcium + cephalin + brain extract) kept under acetone and prepared for use by evaporating acetone and redissolving it in 0.9 per cent NaCl at pH 7.25.

	THROMBIN (C.C.)	DISTILLED WATER (C.C.)	HEPARIN (MG. IN 0.25 C.C.)	"ALBUMIN" (C.C.)	FIBRINOGEN* (C.C.)	CLOTTING TIME (38° C.)
1	0.5	0.5	-	-	1	14 sec.
2	0.5	0.25	-	0.25	1	18 sec.
3*	0.5	0.25	-	0.25	1	33 sec.
4	0.5	0.25	0.05	-	1	23 sec.
5	0.5	-	0.05	0.25	1	>4 hr.
6†	0.5	0.25	0.05	0.25†	1	26 sec.

*Fibrinogen added immediately, except in No. 3 where the addition was deferred for one hour; the increase in clotting time is scarcely significant in comparison with the immediate antithrombic effect noted in No. 5.

†A weak solution of dialyzed crystalline serum albumin (McMeekin) was used in No. 6.

As to the manner in which heparin acts, Howell and Holt (1918)³³ postulated a dual role. The first or "antiprothrombic" action (so-called) is the prevention of conversion of prothrombin to thrombin. This has recently been denied by at least four groups of workers (Mellanby, Quick, Smith and co-workers, and Astrup), but the last two admit that it can occur in the presence of an accessory plasma factor, possibly identical with the second mechanism (vide infra). We have³⁶ pointed out that all these recent workers used strong aqueous thromboplastins in converting the prothrombin to thrombin. If, however, only the isolated phospholipid is used, the classical antiprothrombic action of Howell is confirmed, without any accessory factor (Table IV).^{*} The inhibitory action, therefore, refers to the thromboplastic system rather than to the prothrombin itself. There is no doubt as to the second mode of action ("proantithrombic" of Howell and Holt) in which inactivation of fully formed thrombin is secured if, and only if, an additional factor, believed to be associated with plasma albumin (Quick) is present (Table V). We have recently performed some preliminary experiments with a pure crystalline serum albumin kindly supplied by Dr. T. L. McMeekin (Harvard) which accords with the findings of the Toronto workers³⁷ in failing to show definite antithrombic action with mixtures of crystalline albumin and heparin. This difference from the crude "albumin" is unexplained.

The real nature and mode of action¹⁴ of "antithrombin(s)" are not fully understood, but much significance attaches to the data of Fischer (Copenhagen)³⁸ showing the ability of heparin to form molecular compounds with proteins and protein split-products to make substances having a shift in their

*Reference 36, Table II.

isoelectric point in the acid direction. In situations where antithrombic factors are definitely demonstrable there can be little doubt as to their effectiveness in retarding in vivo as well as in vitro blood clotting.

SUMMARY

Prolongation of clotting time may contribute to those hemorrhagic states in which we can demonstrate (or postulate) either prothrombin or thromboplastin deficiencies or an excess of antithrombic factors. Calcium may be excluded from practical consideration. Factors such as fibrinogen and platelet defects play a role in determining the effectiveness of clotting and thrombosis in the arrest of hemorrhage. All these are controlling mechanisms, and the prior causative factors, including capillary injury, must also receive the fullest consideration.

HEMOLYTIC ANEMIA*

RUSSELL L. HADEN, M.D., CLEVELAND, OHIO

EVERY anemia results from a loss of balance between red blood cell formation and red blood cell destruction. A hemolytic anemia is one due to a more rapid destruction of erythrocytes than the bone marrow can replace. The normal method of disposal of worn-out, or otherwise injured, cells is by hemolysis. Almost a trillion, or one twenty-fifth, of all the circulating erythrocytes are so disposed of each day. Normally a delicate balance is maintained between erythrocyte formation and the hemolysis of cells. If hemolysis is excessive from any cause, an anemia results.

A normal mature erythrocyte is a discoid cell composed of water, protein, lipid, and salts. Ponder,¹ after reviewing various theories concerning its structure, concludes that, "The conception that the red cell possesses a distinct structural membrane of considerable strength composed of protein, lipid, and perhaps other substances, that the interior of the cell contains a fine network, and that the hemoglobin is contained in the meshes of this fine stroma, perhaps partially adsorbed to it, meets all arguments." Ponder² emphasizes that this shape makes it necessary to consider the cell as being in a state of considerable and permanent strain. This strain may be due to the surface membrane of protein and lipoids which cannot be demonstrated histologically, or be dependent on the nature of the internal stroma. When the strain is released, the cell assumes a spherical form, as a result of the action of surface tension.

Every red blood cell wears out in time. The exact span of life is unknown. Perhaps thirty days is an average. The precise factors influencing the normal termination of the activity of an erythrocyte and the method of its disposal are not clear. The spleen plays a major role in destruction and seems to be the graveyard for the worn-out cell. When a cell has been injured by the normal wear and tear of use, or by some toxic agent, the cell tends to become spherical from the loss of the surface or intracellular forces which normally hold it as a biconcave disk. Such a change seems the first stage of hemolysis. There is much evidence that a substance, lysolceithin,³ which is formed in the spleen and makes erythrocytes spherical, aids in the normal hemolysis of old and injured cells and, at times, may be a factor in abnormal hemolysis.

The erythrocytes are taken out of circulation by the reticulo-endothelial cells. The cell stroma is completely broken up. The hemoglobin contained in the stromatin does not return to the blood as such but is disintegrated by the reticulo-endothelial cells. The globin-hematin combination in the hemoglobin molecule is split up, the iron in the hematin fraction is set free, and bilirubin is formed.

*From the Cleveland Clinic.

There are no end products of the stroma which can be identified in the laboratory. The hemoglobin is quantitatively converted into bilirubin, however, so if the amount of bilirubin formed is known, the amount of hemoglobin destroyed and, indirectly, the number of erythrocytes lost, can be calculated. The only exact way to measure bilirubin so formed would be to analyze the total bile excretion. However, there is no practical way to collect this. Fortunately, it is difficult for the liver or the kidneys to excrete the bilirubin formed from hemoglobin because it is bound to protein. With obstructive jaundice there is a retention of bile salts as well as bilirubin. These raise the surface tension and thus free the bilirubin from combination with protein and make it easy to excrete. Since the bilirubin formed from the hemoglobin set free when erythrocytes are hemolyzed tends to be retained, the amount and rate of red blood cell destruction are indirectly determined by measuring the amount of pigment in the plasma, provided there is no disease of the biliary tract.

In almost every hemolytic anemia due to the excessive destruction of erythrocytes, the bone marrow tries to compensate for the increased loss of cells. It is possible that the increase in cell destruction may be fully compensated for by a higher rate of delivery of new cells from the marrow. It is difficult and rare for this to continue. Even with the most active marrow there is usually still an anemia. The usual finding in a hemolytic anemia is both an increase in the bile pigments of the plasma paralleling the rate of cell destruction, and a high reticulocyte count, indicating that cells are being delivered very rapidly from the marrow. The red blood cell count and hemoglobin measure only the balance between formation and destruction at the time the count is made. The reticulocyte count, together with the total red blood cell count, gives indirectly the survival time of the erythrocyte in the circulation. Thus, with a normal red blood cell count of five million per cubic millimeter and a reticulocyte count of 0.5 to 1 per cent, the mean span of life of the red corpuscle is about thirty days. If the reticulocyte count is high, such as 15 to 25 per cent, it is apparent that the mean span of life can be only one to three days.

Since the cells are being removed largely by the spleen, this organ is nearly always enlarged from overactivity. The clinical picture, then, of a hemolytic anemia is anemia with jaundice and an enlarged spleen, with absence of obstruction of the bile ducts. On examination of the blood, besides the anemia, the bile pigments of the plasma are increased, the reticulocyte percentage is increased, and usually there are numerous red blood cells with nuclei, diffuse basophilia, and nuclear remains, such as Isaacs' granules and Howell-Jolly bodies.

Since the bone marrow is overactive in supplying an excessive number of red blood cells, marrow which is normally yellow becomes red through active erythropoiesis. In patients dying of a hemolytic anemia, which has persisted long enough for the low bone marrow to react, the marrow throughout the body may be red. A bone marrow puncture shows excessive erythropoiesis also, as indicated by the large number of cells of the erythrocyte series (Fig. 1).

Abnormal hemolysis may be due to the presence of agents toxic for the erythrocyte in the blood plasma. These may be: (1) toxins resulting from bacterial growth; (2) immune hemolysins, such as occur in the transfusion of

54691

incompatible blood groups or in paroxysmal hemoglobinuria from cold; or (3) chemical poisons, such as the phenylhydrazine group or snake venoms. In the group of chemical poisons may be included those formed in the body as an allergic response to an antigen, as in favus-bean poisoning. The mechanism of red blood cell destruction by malarial and other intracellular parasites is obvious though different from the preceding group. Damaged cells are taken out of circulation by the spleen. Many other chemical substances will actively destroy red blood cells. Among these are acids, alkalies, bile salts, saponin, and snake venoms. Hemolysis is rapid in hypotonic salt solutions.

Fig. 1.—Film of marrow obtained by sternal puncture. Note the large number of immature cells of the erythrocyte series.

An increased hemolysis of cells may also result from a defect in the cell itself, rendering it more easily destroyed. The defect may be an abnormal shape of the erythrocyte or an imperfection in quality of the cell stroma which makes it more easily destroyed. Sometimes abnormal hemolysis seems to be due to a perverted activity of the reticulo-endothelial cells, especially in the spleen.

It is difficult to make a satisfactory clinical classification of the hemolytic anemias. One possible grouping is as follows:

- I. Increased hemolysis from excessive destruction of cells damaged by:
 - A. Chemical agents, as phenylhydrazine.
 - B. Bacterial toxins, as in gas gangrene.
 - C. Immune hemolysins, as in transfusion reactions.
 - D. Parasites, as in malaria.
- II. Increased hemolysis due to excessive removal of congenitally abnormal cells:
 - A. Congenital abnormality of shape.
 1. Spherocytic anemia (congenital hemolytic jaundice).
 2. Sick-cell anemia.
 3. Oval-cell anemia.

- B. Congenital abnormality of structure.
 - 1. Erythroblastic anemia of Cooley.
 - 2. Sickle-cell anemia.

- III. Increased hemolysis from abnormal hemolytic activity of spleen or other parts of reticulo-endothelial system.
- IV. Increased hemolysis from unknown cause, as in paroxysmal nocturnal hemoglobinuria (Marchiafava-Micheli type) and the idiopathic types of hemolytic anemia.

CHANGES IN MEASUREMENT OF THE ERYTHROCYTE OF MAN ON HEMOLYSING IN HYPOTONIC SODIUM CHLORIDE SOLUTION

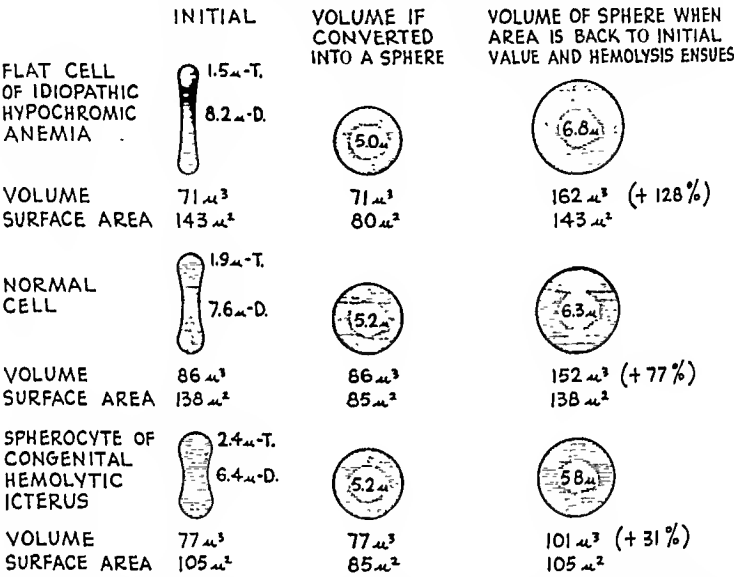

Fig. 2.—Changes in measurement of the erythrocyte of man on hemolyzing in hypotonic sodium chloride solutions. The flatter the cell, the greater the volume the cell can reach before the original surface area is reached as the cell becomes spherical and increases in volume.

The exact mechanism of hemolysis varies with the hemolyzing agent. In hypotonic salt solutions the contents of the cell are altered by the excess of water. The cell becomes spherical, the membrane becomes permeable, and the cell swells as water is taken up. In time, the cell ruptures. Such is the mechanism of hypotonic hemolysis. With hemolysis by a chemical agent, some constituent of the cell is affected so that the structure is altered and the cell breaks up. Thus, saponin and bile salts act on the protein of the cell, while snake venom affects the lecithin and produces lysolecithin, an active hemolytic agent. In every instance there is an alteration of cell structure. If the cell is abnormal at the start, it is apparent that the hemolysis may take place much more easily than in a normal erythrocyte.

With hypotonic hemolysis, the cell changes from a biconcave disk to a sphere during the process of dissolution.⁴ The flatter the cell, the greater the increase in volume possible before the cell membrane, which cannot be stretched, will rupture. Thus a flat cell, with a volume of 71 cubic microns, a diameter of 8.2 microns, and a thickness of 1.5 microns, can increase in volume 128 per cent

before the membrane ruptures. A normal cell will increase 77 per cent. On the other hand, a cell with a volume of 77 cubic microns, a diameter of 6.4 microns, and a thickness of 2.4 microns, can be increased in volume only 31 per cent before the cell is a sphere and further tension ruptures the membrane (Fig. 2). It is this fact that explains the increased fragility in hypotonic solutions of the microspherocytes characteristic of congenital hemolytic jaundice.⁵ Such cells cannot have the normal increase in volume without putting the membrane on tension sufficient to rupture it.

Whenever the cell structure is altered in other ways, there is a tendency for the cell shape to change from the biconcave form to the sphere. The action of lysolecithin, which is normally present and which may be the normal agent in red blood cell hemolysis, is to make the cells spherical.³ Likewise, spherocytosis may be characteristic of the hemolytic anemia due to leucemia, Hodgkin's disease, or acetylphenylhydrazine. On the other hand, the most marked hemolytic anemia may occur without spherocytosis (Table IV). Here the cells break up without going through changes in shape already described. Perhaps here the essential element is overactivity of reticulo-endothelial cells which destroy erythrocytes without changing them chemically. Ham⁶ has shown recently that a change in reaction may also greatly influence the speed with which cells break up.

The two factors in increased hemolysis may be summarized:

- I. Increased hemolysis of normal cells damaged by foreign agents, namely:
 - a. Chemical poisons, such as phenylhydrazine, sulfanilamide, or snake venom.
 - b. Parasites, as the malarial protozoan.
 - c. Bacterial toxins, as in gas gangrene.
 - d. Amboceptor and complement reactions, as in transfusion of incompatible blood, or in paroxysmal hemoglobinuria.
- II. Increased activity of the spleen.

The action of the spleen may be the normal phagocytic activity on damaged cells as described above, or on abnormally shaped, or imperfect cells as in spherocytosis (congenital hemolytic icterus), sicklecytosis, or ovalocytosis. In some cases there seems a true perverted activity of the spleen and perhaps of other parts of the reticulo-endothelial system, as in Hodgkin's disease and leucemia. Thus, the shape and structure of the cell, the activity of the spleen, and the presence of substances toxic for erythrocytes must be considered as possible factors in the production of every hemolytic anemia.

Congenital hemolytic icterus is the best known example of a chronic hemolytic anemia. This disease may continue active for many years. Here there is characteristically a chronic anemia, with acute exacerbations, jaundice, reticulocytosis, and an enlarged spleen. All the signs and symptoms of the disease are due to excessive destruction of red blood cells. The erythrocytes have two distinguishing characteristics. In the first place, they are thicker than normal in relation to diameter. Since the diameter is usually less than normal with little variation from normal in volume, the cells are usually spoken of as micro-

spherocytes. Some of the cells are true spherocytes, but most of them are simply thicker than normal (Fig. 3). All observers are agreed on this fundamental characteristic of the cell in congenital hemolytic icterus. The second characteristic property of the red blood cell is its increased fragility in hypotonic solutions of sodium chloride. This finding is less characteristic than the spherocytosis, since factors other than shape of the cell may influence fragility. A thick cell with a more than resistant envelope may show little if any change in fragility. The cell measurements in ten typical cases of congenital hemolytic icterus are shown in Table I.

TABLE I
THE ERYTHROCYTE IN CONGENITAL HEMOLYTIC ICTERUS

NO.	COUNT	MEAN VOLUME	MEAN DIAMETER	MEAN THICKNESS	VOLUME THICKNESS INDEX	DIAMETER-THICKNESS RATIO	RETICULOCYTES	FRAGILITY	ICTERUS INDEX
	millions	cubic microns	microns	microns			per cent	% $\frac{\text{NaCl}}{100}$	units
1.	2.65	80	6.4	2.5	1.51	2.6:1	10.5	58-39	35
2.	1.82	77	6.5	2.3	1.44	2.8:1	22.1	68-38	20
3.	3.73	84	6.0	3.0	1.73	2.0:1	6.5	68-38	15
4.	3.08	87	6.6	2.5	1.54	2.6:1	14.9	66-40	15
5.	2.13	76	6.4	2.4	1.46	2.7:1	14.7	64-36	25
6.	2.37	111	7.3	2.6	1.45	2.8:1	31.0	56-42	15
7.	2.65	105	7.5	2.4	1.27	3.1:1	10.8	56-38	5
8.	3.07	91	6.5	2.7	1.67	2.4:1	17.9	45-34	25
9.	4.43	85	7.2	2.1	1.18	3.4:1	3.7	44-32	8
10.	3.99	85	6.8	2.4	1.38	2.8:1	4.8	47-39	6

As the name indicates, there is a large hereditary element in spherocytosis. Cases may be sporadic, however, without any evidence of the disease in relatives. The degree of spherocytosis may vary greatly. Thus, in a recently case, a 2-year-old child had an extreme spherocytosis, while the mother had only a mild spherocytosis which was revealed by careful cell measurements. The congenital defect is really an anatomic one, since it represents a variation in the normal shape. It is often accompanied by other anatomic defects, especially steple skull.

From the clinical standpoint, the important features of congenital hemolytic icterus or spherocytic anemia are the chronic anemia, the constant, though mild, jaundice, and the enlarged spleen. Infections and other unknown factors may greatly speed up the hemolytic process, causing the so-called crises during which the anemia is more severe, the icterus is more intense, and the spleen is larger. If there is a family history of jaundice and an enlarged spleen, the picture is complete.

The two characteristic findings in relation to the red blood cell already mentioned, namely, the spherocytosis and the increased hypotonic fragility, have usually been considered as separate defects of the red blood cells. Chauffard⁷ regards these two features as evidence of the lessened vitality of the cells. Meulengracht⁸ is of the opinion that they are regeneration phenomena secondary to the increased bone marrow activity. Gänsslen⁹ expressed the belief that there is a primary defect in the marrow which makes it incapable of supplying cells of normal size and resistance. Naegeli¹⁰ always contended that the defects repre-

Fig. 3.—The mean red blood cell in congenital hemolytic icterus compared with the normal biconcave disk and the flat, "wedding-ring" erythrocyte of hypochromic microcytic anemia. Note the characteristic increases in thickness, decrease in diameter, with little change in volume.

Fig. 4.—Changes in the shape of the erythrocyte in congenital hemolytic icterus compared with the normal in hypotonic hemolysis. The more marked the spherocytosis, the closer the cell is to the hemolysis point. The fragility thus varies directly with the degree of spherocytosis.

sent a congenital anatomic abnormality of the erythrocyte comparable with other anatomic congenital defects. No one seems to have correlated the spherocytosis and the increased fragility.

There is a direct relationship between the shape of the cell and hemolysis.⁵ Ponder has demonstrated that this depends fundamentally upon how much the volume of the cell can increase without stretching and rupturing the covering membrane.¹¹ This point is best illustrated by comparing the changes in a normal red blood cell and that of congenital hemolytic icterus (Fig. 2) in hypotonic solutions of sodium chloride. Note again the increase in volume by immersing in hypotonic solution of 77 per cent (from 86 μ^3 to 152 μ^3) of the normal cells as compared with 31 per cent in a patient with congenital hemolytic icterus. The intensity of congenital hemolytic icterus varies directly with the degree of spherocytosis. The more spherocytic the cell, the nearer it is to the hemolysis point (Fig. 4).

The relation of the shape of the cell to hypotonic fragility is well illustrated by the study of the erythrocytes of different animals. It has long been known that the fragility of the red blood cells in hypotonic solution varies greatly in different animals. Vallery-Radot and Lheritier¹² first pointed this out and concluded that the fragility parallels the diameter of the cells. In Table II are shown the measurements of the mean cell of a group of animals as measured by Emmons,¹³ and the fragility for the same animals as determined by Vallery-Radot and Lheritier. It is apparent that the fragility varies with the globularity of the mean cell; hence there must be a direct relationship of the two factors.

Goat	4.0	1.95	25	2.1:1	0.72-0.74

Spherocytosis is the one absolutely constant finding in our group of 30 cases of congenital hemolytic icterus. The diagnosis is not justified unless this characteristic cell is found. The seriousness of the disease can be measured by the extent of the spherocytosis. Is this shape related to increased removal of cells from the blood stream by the spleen in congenital hemolytic icterus? The immediate cause of the anemia is hyperactivity of the spleen, since the symptoms of the disease are all relieved by splenectomy. Spherocytosis always persists after removal of the spleen, although it is less marked than before operation.

The findings in eight patients studied after splenectomy are shown in Table III. In every instance the anemia, jaundice, and reticulocytosis were entirely relieved. The decreased cell diameter and the spherocytosis were still present, though to a less marked degree than before operation. It is apparent

from the beneficial results of splenectomy that the anemia is due to the activity of the spleen in filtering out spherocytes. The exact mode of action of the spleen is unknown. The spleen might make the cells more spherocytic and thus more susceptible to hemolysis, perhaps through the action of lysolecithin, as suggested by Bergenhem and Fahraeus.³ Recently I measured the diameter of the cells on a film of blood obtained from the pulp of a spleen immediately after removal for congenital jaundice. The mean cell diameter was 5.8 microns, while the mean diameter of the circulating cells determined at the same time was 6.1 microns. Gripwall¹⁵ has shown also that the cells from the splenic vein show a more pronounced spherocytosis and increased fragility as compared with peripheral blood.

Fig. 5.—The characteristic changes in the blood after splenectomy for congenital hemolytic icterus. Note the fall in the icterus index to normal and the disappearance of the reticulocytosis. The hypotonic fragility changes very little. The hemoglobin gradually rises.

The characteristic changes in the blood after splenectomy for congenital hemolytic icterus are shown in Fig. 5. The icterus index returns to normal, and the reticulocytosis disappears quickly. There is a gradual steady rise in hemoglobin. The increased fragility of the red blood cells persists to a lesser degree. Heilmeyer¹⁷ has made the same observations. The spleen might also affect the cells in some other way so as to injure the cell envelope and thus make it more susceptible to hemolysis. The spherocytes of congenital hemolytic icterus are more susceptible to destruction by heat than are normal cells. The blood of three patients who had had a splenectomy for congenital hemolytic icterus, the blood of two patients who were suffering from the disease but who were not splenectomized, and the blood of a normal individual were heated in a water bath for three hours. There was only a trace of hemolysis in the normal blood. The blood of the splenectomized patients showed well-marked hemolysis, but much less hemolysis than the blood of the patients with the active disease. The mean cell diameter in the splenectomized patients was 6.9, 6.7, and 6.8, with

a volume thickness index of 1.31, 1.43, and 1.33. The mean cell diameter of the other patients was 6.6 and 6.4, with a volume thickness index of 1.54 and 1.46. The hemolysis was most marked with the mean cell diameter of 6.4. Another patient with a mean cell diameter of 6.2 showed the most marked hemolysis when his blood was heated for three hours at $-12^{\circ}\text{C}.$, with the control showing only faint hemolysis.

The persistence of the spherocytosis and increased fragility after splenectomy, without clinical evidence of disease, shows that the bone marrow is still supplying cells thicker than normal. The fact that the cells are more spherocytic, more fragile, and more susceptible to hemolysis by heat before the spleen is removed proves that the spleen in some way affects the cell. This may be caused by changing the cell shape only or by affecting the constituents of the cell so that it becomes more spherocytic and less resistant. Perhaps the action of the spleen on the spherocytic cell is the normal action on every cell. In any event, this is sufficient in congenital hemolytic icterus to cause destruction of the cell and a consequent anemia. Hawksley¹⁴ and Gripwall¹⁵ have emphasized that there is a splenic factor, as well as a congenital abnormality of shape, in the causation of the anemia. Doan, Wiseman, and Erf¹⁶ are of the opinion that the spleen is the chief organ in the hemolytic process. Heilmeyer¹⁷ considers the spleen entirely responsible for spherocytosis and increased hemolysis.

There are evidently factors other than shape affecting the fragility of the cell in congenital hemolytic icterus. While there is a striking parallelism between the resistance of the cells to hemolysis in hypotonic sodium chloride solution and the degree of spherocytosis, there are also exceptions to this rule. Thus in one patient with a marked spherocytosis (volume-thickness index 1.67) the red blood cells have repeatedly shown a fragility within the normal limits or little beyond it. It is evident that the envelope of this patient's cells is more resistant than the usual cell with such a shape. The cells of another patient studied immediately after a hemolytic crisis, during which transfusions were given, were more resistant to hypotonic hemolysis than would be expected from the degree of spherocytosis. Later there was a great increase in fragility with little change in cell shape.

While spherocytosis is a constant finding in congenital hemolytic icterus, spherocytosis may be present without increase in fragility, and the increase in fragility may not parallel the spherocytosis. Just what are the factors influencing the strength of the cell membrane or the stability of the stroma making it more resistant to release of strain is not clear. There may well be some qualitative variation in the protein or lipoids of the cell, or even a difference in the thickness of the cell envelope. The normal protective action of the plasma may vary also. Any such changes might afford a protective action against lysis.

In congenital hemolytic icterus there is a microspherocytosis throughout life. After splenectomy the anemia disappears, and the spherocytosis is less marked. Spherocytosis may be seen under other conditions also. I have observed marked spherocytosis in three patients with outspoken leucemia. The fragility of the cells in hypotonic solutions was increased as one would expect from the shape of the cells. In each instance the spleen was enlarged, and in two instances it was removed without influencing the extent of the anemia or the

course of the disease. Another patient with a probable sarcoid of the lung had spherocytosis and increased fragility of varying intensity, depending on the degree of activity of the lung disease. The patient has made a complete recovery. The marked hemolytic anemia has disappeared, as has the spherocytosis. It seems apparent, as emphasized by Ponder, that a toxic process may so affect the cell as to make it spheroid. In the hemolytic anemia produced by phenylhydrazine, I have demonstrated a spherocytosis which is only an evidence of damage to the cell, with release of the internal strain and the taking on of a spherical form.

Fig. 6.—Changes in the blood of patient showing acquired spherocytosis of unknown origin after splenectomy. The hypotonic fragility is unchanged. The hemoglobin changes little and the reticulocytosis persists. The splenectomy did not alter the fatal course of the disease. The spherocytosis, as indicated by the volume-thickness index, becomes more marked.

Dameshek and Schwartz¹⁸ studied the changes taking place in the red blood cell when the guinea pig is injected with antiguinea pig hemolytic serum. The cells of the animal injected become spherocytic and show increased fragility in hypotonic sodium chloride solution. They further demonstrated isohemolysins of the immune body type in three patients with acute hemolytic anemia. In one spherocytosis and increase in fragility were marked. All three were relieved by splenectomy. Dameshek and Schwartz conclude from their experimental studies that hemolytic anemias are due to hemolysins and that the spherocytosis is due to hemolysis and not primarily to an abnormal type of cell. These observations only show that spherocytosis can be acquired. It is very doubtful whether they have any application in congenital hemolytic icterus. The spherocytosis here evidently results from the reaction of the cell to the injury by hemolysis.

I recently studied one patient with marked spherocytosis and a great increase in fragility who constantly had large amounts of hemolysin in the blood plasma. When first seen this patient had a marked anemia, his volume thickness index was 1.29, and hemolysis began in 0.60 per cent sodium chloride solution. There

was no family history suggesting congenital hemolytic icterus, the blood of other members of the family was normal, and the patient had been entirely well until the onset of his present illness. The anemia was so marked and the response to therapy so poor that splenectomy was done. There was some improvement for two months, but the reticulocytosis, the hemolysins, the increased fragility, and the spherocytosis persisted. The anemia became progressively worse. The patient died of the anemia five months after the splenectomy. Autopsy showed no trace of a spleen. It is apparent that the spherocytosis and anemia here were not due to the spleen. This patient evidently had an acquired spherocytosis, and the hemolytic anemia was not dependent on any abnormality or activity of the spleen. The changes in the blood (Fig. 6) are in marked contrast to those observed following splenectomy for congenital spherocytosis (Fig. 5).

Sickle-cell anemia and the erythroblastic anemia of Cooley are also good examples of chronic hemolytic anemia. In these anemias there is evidently an inherited defect in quality of the stroma, so that the cells disintegrate and are removed by the spleen. The curious shapes observed in sickle-cell anemia are simply the expression of this abnormality of the stroma. As the stroma changes, especially with anoxemia, the cell takes on the characteristic sickle form. These diseases must be looked upon as congenital defects in quality of the stroma. There may be other unrecognized congenital defects in the stroma.

I have recently observed a mother and two children, all showing an identical hemolytic anemia. The mother's mother had died with jaundice, anemia, and enlarged spleen at an early age. All three patients showed icterus, reticulocytosis, and free hemoglobin in the blood plasma without hemoglobinuria. Repeated study of the red blood cells showed no increase in hypotonic fragility and no spherocytosis. The cells hemolyzed rapidly, however, under conditions in the laboratory which would not produce hemolysis of normal cells. A splenectomy was done for the mother without influencing the hemolytic process (Fig. 7). It seems apparent that the only logical explanation for such findings is a congenital weakness of the erythrocyte which makes it more susceptible to hemolysis. The presence of free hemoglobin in the plasma should have shown that splenectomy was contraindicated.

The anemia of malaria and other protozoan diseases in which the red blood cells are invaded and destroyed by parasites needs no discussion. Likewise, there is nothing unusual about the anemia dependent on the destruction of cells by various poisons which affect the different constituents of the red blood cell. The anemia of snake venom poisoning is one of the most interesting of this group, because it has been proved that the venom removes the unsaturated fatty acid from the lecithin molecule, thus producing lysolecithin which is a violent hemolytic agent.

As red blood cells are destroyed, hemoglobin must be set free. It is a curious fact that even with most marked hemolytic crises in congenital hemolytic icterus no free hemoglobin is ever demonstrated in the blood plasma. Likewise, in a sickle-cell anemia, Cooley's anemia, and the so-called idiopathic hemolytic anemia, free hemoglobin is not demonstrable. In this group of cases it seems apparent that the cells are destroyed within the spleen or other parts of the reticulo-endothelial system. It is in these cells also that hemoglobin is disintegrated with the production of bilirubin.

In another group of hemolytic anemias, however, hemoglobinuria is a striking clinical feature of the patient's disease. Thus, in transfusions with incompatible blood, by the action of isohemolysins, hemoglobin is set free; if it rises above a certain level in the blood plasma, it is excreted by the kidneys. The paroxysmal hemoglobinuria due to cold is again due to the overflow of free hemoglobin through the kidney as a result of the rapid destruction of cells by an amboceptor-complement reaction. In such instances the hemoglobinuria is not due to the hemolysis of cells alone, as with even more rapid destruction in the crises of congenital hemolytic jaundice no hemoglobin is present in the plasma. The essential difference here seems the fact that the hemolysis is taking place in the circulating blood rather than in the spleen or other tissues where the hemoglobin is disposed of without becoming free in the blood plasma. It is apparent that splenectomy is not indicated if the cells are hemolyzing in the plasma unless the spleen is setting free a toxin which has never been proved. It is possible also that the hemolysis in such cases is due to the loss of normal protective power of the blood plasma.

Fig. 7.—Changes in the blood of a patient with hemolytic anemia without spherocytosis. The patient had hemoglobinemia. The splenectomy did not alter the course of the disease. Note the persistence of bilirubinemia and reticulocytosis and absence of rise in hemoglobin.

One type of hemolytic anemia, first described by Marchiafava and Micheli in Italy, seems a definite clinical entity.⁶ In this type the patients have not only hemolytic anemia, but also constant hemoglobinemia and hemoglobinuria. The hemoglobinuria is described as paroxysmal and nocturnal and seems to be characteristic of earlier stages of the disease and of milder cases. I have examined the blood of two patients and observed another. The blood of one patient has been studied repeatedly from every standpoint. Such cases have no family history of the disease. The condition is usually not manifested until after adolescence and may develop at any age. No spherocytosis is present. Ham⁶

has demonstrated that the cells are more susceptible to hemolysis with weak solutions of acids than are normal cells. It seems evident that the disease is inherent in the red blood cells. The defect is certainly in quality and not in shape. The spleen has been removed from several patients without influencing the course of the disease. Here again it seems that the presence of free hemoglobin indicates that the defect is in the red blood cells and is such as to allow them to hemolyze in the circulation. If this is true, a splenectomy should not influence the disease. This has been the experience of everyone with splenectomy in this type of hemolytic anemia. No other treatment has been found of value.

There is a final group of hemolytic anemias which we speak of as idiopathic. Some are probably due to infections; some to the presence of unidentified hemolytic agents. The spleen seems at fault in others. Fortunately, this group is small. Splenectomy is usually justified if hemoglobinemia is not demonstrated. The results are variable.

SUMMARY AND CONCLUSIONS

A hemolytic anemia is due to an excessive destruction of red blood cells beyond the compensatory capacity of the bone marrow to deliver new cells.

The normal red blood cell has a delicate structure which may be injured in many ways. The biconcave shape results in a state of strain in the stroma.

As erythrocytes are destroyed, iron is set free, and bilirubin is formed as the end product of hemoglobin destruction.

The clinical picture of a hemolytic anemia is an anemia with jaundice and an enlarged spleen.

The laboratory study in a hemolytic anemia shows a high reticuloocyte count from excessive marrow activity, a high icterus index, and a hyperplastic bone marrow.

The excessive destruction of red blood cells in a hemolytic anemia may result from (1) damage to the red blood cells, (2) an abnormal shape of the red blood cells, (3) a congenital defect in quality of stroma, or (4) an overactivity of the spleen.

The mechanism of hemolysis varies with the hemolytic agent.

When a cell is injured, it tends to assume a spherical shape since the strain incident to the biconcave shape is released.

The most characteristic and clinically important hemolytic anemia is congenital spherocytosis or congenital hemolytic icterus. The inherited defect here is the abnormal shape of the red blood cell.

A spherocyte is more easily hemolyzed than is a biconcave disk.

There is a direct relationship between hypotonic fragility of the red blood cell in spherocytosis and its shape. A sphere has a smaller surface area in relation to volume, so it can undergo less stretching before hemolysis occurs than a biconcave disk.

The anemia disappears after splenectomy in congenital hemolytic icterus. The spherocytosis persists, but it is less marked.

Spherocytosis may be acquired since an injury to cells by any agent may cause it. Acquired spherocytosis is characterized by increased fragility of cells.

In many hemolytic anemias there is no abnormality of shape so the hemolysis must depend upon other factors, such as an abnormal reaction, changes in the cell membrane, stroma, or constituents of the plasma, or abnormal reticulo-endothelial activity.

In sickle-cell anemia and in the erythroblastic anemia of Cooley, there seems to be a congenital defect in the stroma which allows the cells to be easily hemolyzed abnormally.

If hemoglobinuria is present in a hemolytic anemia, the cells are being destroyed in the circulating blood and not in the spleen.

With hemoglobinemia and hemoglobinuria, splenectomy is contraindicated.

PRESERVED BLOOD "BANKS" IN RELATION TO TRANSFUSION IN THE TREATMENT OF DISEASE*

JOHN A. KOLMER, M.D., PHILADELPHIA, PA.

SINCE blood transfusion has come into wider and wider use not only in the treatment of hemorrhage, surgical shock, and the anemias, but also in the treatment of the prothrombin deficiencies, hemorrhagic dyscrasias, acute and chronic infections, with special reference to the septicemias, as well as many other disease states, and, since the use of preserved blood in "banks" has become increasingly popular because of its several advantages, it is my purpose to discuss briefly and concisely the value of different preservatives and to point out the limitations of preserved blood as a therapeutic agent.

In the United States human blood is commonly preserved in "banks" by the addition of 14 c.c. of a sterile 2.5 per cent solution of chemically pure sodium citrate in physiologic saline solution to each 100 c.c. of blood, with preservation at 4° to 6° C. in a refrigerator. This gives a 0.35 per cent concentration of sodium citrate for the prevention of coagulation, and after typing, sterility, and Wassermann tests, the blood is ordinarily available for transfusion over a period of ten days to several weeks.

Physiologically, and according to clinical experience, such preserved citrated blood is apparently satisfactory for the restoration of blood volume and is superior to saline, glucose, and acaemia solutions in the treatment of severe traumatic hemorrhage and shock. Whether or not the erythrocytes are sufficiently preserved to carry on internal respiration is debatable; likewise the question as to whether or not the platelets and prothrombin are sufficiently preserved for the treatment of the thrombocytopenic purpuras, other hemorrhagic dyscrasias, and the hemorrhage of jaundice.

It is sometimes stated that the chief value of blood transfusion in the treatment of septic states, with or without associated septicemia, is to combat the secondary anemia, and that it is not indicated or required until or unless the hemoglobin is reduced to about 40 per cent, with a corresponding reduction in erythrocytes.

With this I do not agree. Septicemia is apparently the result of a breakdown or exhaustion of the normal clearing mechanism of the blood; not infrequently the result of continuous accession of bacteria and their toxic products from foci of infection of the fixed tissues. I have gradually gained the conviction that one of the most important reasons for frequent transfusions in the treatment of septic states, and especially those with an associated septicemia, is to furnish specific and nonspecific immune substances in the blood of the donor, which may have become reduced or exhausted in the hard-pushed patient or recipient. Furthermore, it is not unlikely that the leucocytes of *fresh* blood

*From the Research Institute of Cutaneous Medicine, Philadelphia.

may serve a useful therapeutic purpose. Therefore, without questioning the value of transfusion in septic states from the standpoint of combating secondary anemia, it seems to me that proper emphasis must be placed upon its possible additional value from the immunologic standpoint, and if this is true, the therapeutic status of preserved citrated blood should be examined from both angles.

Briefly and in general terms, it may be stated that normal or natural resistance and immunity to infection are due in part to specific antitoxins and such sensitizing antibodies as agglutinins, opsonins, and bacteriolysins that may be present in the blood. To these, from the nonspecific standpoint, must be added complement, leukins (from leucocytes), and plukins (from platelets). Among these, the opsonins are of particular importance because of the role they play in phagocytosis, not only by the microphages of the blood and fixed tissues, but also by the cells of the reticulo-endothelial system. Furthermore, agglutinins likewise facilitate both phagocytosis and bacteriolysis in vivo and complement is especially important in both particulars, while leukins and plukins are apparently largely responsible for the normal nonspecific bactericidal activity of the blood. Indeed, it would appear that the chief therapeutic value of non-specific immunotransfusions conducted by the intravenous injection of the donor with 100 million killed typhoid bacilli in vaccine a few hours before transfusion is due in part, both to the transfer of more than normal numbers of leucocytes from donor to patient and to additional amounts of these normal or natural non-specific bactericidal substances.

Certainly we have ample data for indicating that these specific and non-specific mechanisms are responsible for the remarkable capacity of the blood for normally clearing itself of organisms and especially because of phagocytosis by the cells of the reticulo-endothelial system. In septic states, especially septicemia, it is a logical deduction that this clearing mechanism is reduced or exhausted. If this is true, one of the purposes of transfusion in treatment should be to supply the hard-pressed patient with as many of these specific and non-specific factors as possible. One cannot now state that natural antitoxins for the several exotoxins of staphylococci and streptococci are reduced or exhausted in acute infections and especially septicemia, but this may be logically inferred. While it is admittedly difficult to measure complement in relation to bacteriolysis, it is comparatively easy to measure it in relation to hemolysis, and I am convinced on this basis that it is frequently reduced below average normal levels in staphylococcus and streptococcus septicemias. Indeed, I believe that one of the purposes of transfusion is to supply the patient with the complement of the donor; and I believe the same applies to opsonins, which likewise have been found to undergo reduction below average normal levels and especially in acute fulminating infections.

If one of the purposes of transfusion in the treatment of septic states is to supply the patient with these specific and nonspecific immunologic principles, in addition to combating secondary anemia, the question at issue is whether or not transfusion supplies them in amounts of therapeutic value, in view of the fact that normal blood admittedly carries but small amounts of these substances. Indeed, the difference of opinion that exists on the clinical value of transfusion in the treatment of acute and chronic infections is largely on this basis. Insofar as specific antibodies are concerned, it would appear that the blood of con-

valescent or actively immunized donors is to be preferred on the basis of supplying larger amounts, and for this reason specific immunotransfusions are always to be preferred when possible.

Furthermore, and especially in relation to preserved citrated blood in "banks" for the treatment of acute and chronic infections, and particularly septicemias, the important question is whether or not immune bodies, as well as functionally active erythrocytes and platelets, are sufficiently preserved to be of value. Most attention has been given the matter of preservation of erythrocytes and the prevention of hemolysis, but as I pointed out in 1939,¹ blood so preserved showed such rapid disintegration of polymorphonuclear neutrophils with reduction in their phagocytic activity, along with rapid disintegration of platelets and gradual loss in bactericidal activity, that preserved citrated blood was considered inadvisable for the treatment of the anemias, hemorrhagic states, and infections, although it was apparently useful in the treatment of acute hemorrhage and surgical shock.

Recently there has been an increasing appreciation of the fact that if dextrose or dextrin is added to preserved citrated blood, sodium penetration and cell swelling are decreased, with inhibition of hemolysis as originally shown by Rous and Turner.² Thus Maisels and Whittaker^{3, 4} reported, not only these effects following the addition of carbohydrates, but also an increase of surface area of the erythrocytes, so that they can tolerate a larger absolute inflow of fluid. Aylward and his colleagues⁵ found that citrate-glucose preservation is superior to citrate alone in delaying hemolysis and retards chemical changes in the cells, leading to an increase of plasma inorganic phosphate with reduced plasma potassium probably due to a lower degree of hemolysis. DeGowin, Harris, and Plass⁶ likewise found that large amounts of isotonic dextrose reduce hemolysis and that erythrocytes better resist the effects of shaking and agitation. Whether or not efforts toward the prevention of hemolysis in preserved blood is a matter of practical importance, although desirable from the standpoint of therapy, cannot be stated; particularly since O'Shaughnessy and his colleagues⁷ have reported that 5 per cent solutions of hemoglobin in Ringer's solution are capable of carrying oxygen and maintaining osmotic pressure although not capable of maintaining life more than thirty-six hours because of rapid removal by the cells of the reticulo-endothelial system.

Belk, Henry, and Rosenstein⁸ have confirmed my observations on the marked and rapid disintegration of granulocytes and platelets in preserved citrated blood, and have showed increased fragility of the erythrocytes, rapid glycolysis, changes in oxygen capacity, and plasma carbon dioxide. They also observed that the transfusion of hemolyzed blood produced jaundice in some cases. Whether or not preservation with dextrin or dextrose with sodium citrate results in better preservation of granulocytes, platelets, and immunologic properties of plasma has required investigation.

Under the circumstances I have thought it advisable to determine the properties of four well-known preservatives (two without and two with carbohydrate) in relation to the fragility, dehemoglobinization, and disintegration of erythrocytes; and in relation to the preservation of leucocytes, with special reference to the polymorphonuclear neutrophils, platelets, prothrombin time, isoagglutinins, complement, and bactericidal activity. Some attention has been

given prothrombin, as based upon examinations employing the method of Howell, but the technique employed for the collection and preservation of blood did not permit the use of the method of Quick. Nor have I included determinations for potassium, since DeGowin and his colleagues⁴ have shown that there is progressive diffusion from human erythrocytes into plasma, reaching the maximum in from fifteen to twenty days, and because variations in sodium, chloride, citrate, and dextrose in preservatives, as well as different temperatures and atmospheres, did not affect the rate of diffusion which cannot be explained by the release of this ion from completely hemolyzed corpuscles. Furthermore, it was found in blood preserved for as long as thirty days that the diffused potassium was neither toxic nor high enough to cause significant changes in the serum potassium of the recipient.¹⁰

Two adult donors were selected belonging to groups A and B and the blood of each was used with the following four preservatives:

(a) *Sodium Citrate (citrate):*

Sodium citrate (dihydric)	2.5 Gm.
Distilled water	100.0 c.c.

14 c.c. of the solution are used with 100 c.c. of blood, giving a final concentration of 0.35 per cent citrate.

(b) *Moscow Institute of Hematology (M.I.H.), as given by Elliott¹¹:*

Sodium chloride	3.5 Gm.
Sodium citrate (dihydric)	2.5 Gm.
Potassium chloride	0.1 Gm.
Magnesium sulfate	0.002 Gm.
Distilled water	500.0 c.c.

100 c.c. of the solution are used with 100 c.c. of blood.

(c) *Modified Ross-Turner (R-T), as described by DeGowin, Harris, and Plasse⁶:*

Solution A: 3.2 Gm. sodium citrate (dihydric) dissolved in 100 c.c. of distilled water.

Solution B: 10.8 Gm. dextrose dissolved in 200 c.c. of distilled water.

For use, 20 c.c. of solution A and 130 c.c. of solution B are mixed with 100 c.c. of blood.

(d) *Maisels and Whittaker (M-W),¹² as described by these authors:*

Sodium chloride	0.43 Gm.
Sodium citrate (dihydric)	1.05 Gm.
Dextrin	8.5 Gm.
Distilled water	100.0 c.c.

For use, 50 c.c. of the solution are mixed with 100 c.c. of blood.

Before use each preservative solution was sterilized in the Arnold sterilizer for one hour on each of two successive days and each was examined for sterility by aerobic and anaerobic cultures.

The mixtures of blood and preservative were kept in a refrigerator at 4° to 6° C., and the following ten examinations were conducted with each within twenty-four hours, three, five, seven, ten, fourteen, and twenty-one days after collection:

1. Macroscopic record of spontaneous dehemoglobinization.
2. Fragility or tonicity of erythrocytes.
3. Total erythrocyte counts.
4. Total leucocyte counts and morphologic changes in the polymorphonuclear neutrophils.
5. Differential leucocyte counts.

6. Platelet counts by the smear method.
7. Prothrombin time of the plasma (Howell method).
8. Preservation of isoagglutinins in the plasma.
9. Complement content of the plasma for sensitized sheep corpuscles.
10. Bactericidal activity of the plasma for *B. typhosus*.

As previously stated, determination of prothrombin time (method of Howell) was used as the method of Quick for prothrombin could not be employed owing to technical conditions. Rhoads and Panzer¹³ stated that blood preserved for a week or more is practically useless in the treatment of acute prothrombin deficiency encountered in jaundiced patients not adequately treated with vitamin K and bile salts. In their opinion, blood in "bank" for three days would probably be of some slight value, but would be so inferior to fresh blood that they recommend that only the latter be used when transfusion is intended to combat the hemorrhagic tendency in jaundice. Ziegler¹⁴ also found that prothrombin decreased over a period of time in preserved citrated blood kept at 34° F. to a level of 40 per cent of original content and states that in cases in which it is desired to raise the prothrombin content of the blood by transfusion, old "banked" blood is not a suitable agent. Quick¹⁵ likewise found that the prothrombin diminishes in decalcified blood and that it is inferior to fresh blood for controlling hemorrhage in jaundice. However, the matter may be of more academic value than practical interest, since it is thought that transfusion even with fresh blood probably raises the prothrombin content of the blood of the recipient by only 6 to 8 per cent.

Not without interest was the question of the persistence of isoagglutinins for erythrocytes in preserved blood in relation to transfusion. Strumia, Wagner, and Monaghan¹⁶ state that the intravenous injection of stored plasma from citrated blood (100 c.c. of 2 per cent citrate to 500 c.c. of blood) at the rate of 5.6 c.c. per minute produces no reactions, even though it is capable of agglutinating the erythrocytes of the recipient in dilutions as high as 1:80. Knott and Koerner,¹⁷ however, state that citrated plasma may retain agglutinins for several weeks when kept at a low temperature. They think it is advisable to test the erythrocytes of the recipient with a 1:50 dilution of stored O plasma before administration, because O plasma sometimes contains agglutinins a and b in high concentration, capable of quickly agglutinating the corpuscles of groups A, B, and AB.

The results of this investigation¹⁸ have shown that:

1. The two carbohydrate preservatives gave better protection of erythrocytes against dehemoglobinization, fragility, and disintegration than the plain citrate and Moscow Institute of Hematology preservatives.
2. Marked reduction of the total leucocytes occurred with all four preservatives within three days, especially due to disintegration of the polymorphonuclear neutrophils, but the two carbohydrate preservatives gave somewhat better preservation than the two without dextrose or dextrin.
3. Marked reduction in the platelets occurred with all four preservatives within three days, but both carbohydrate preservatives gave somewhat better preservation than the two without dextrose or dextrin.

4. A slight decrease in prothrombin time (Howell) was observed with the plasmas of all preserved bloods within the first twenty-four hours of collection of blood, presumably due to disintegration of platelets. During the following three to seven days this was followed by an increase, presumably due to loss of prothrombin.

5. The isagglutinins showed no decrease during the first ten days with all four preservatives, but showed some diminution after fourteen and twenty-one days, which was somewhat less marked with the two carbohydrate preservatives.

6. Complement was well preserved by all four preservatives for the first seven to ten days.

7. The bactericidal activity of the plasmas for *B. typhosus* was well preserved by all four preservatives for seven days, following which rapid deterioration occurred.

It is apparent, therefore, that none of the four preservatives employed in this investigation afford adequate protection of the polymorphonuclear neutrophilic leucocytes and platelets, and that this phase of blood preservation has not received the attention it deserves in relation to the transfusion treatment of the acute and chronic infections as well as, possibly, in relation to the hemorrhagic states due to prothrombin deficiency.

Possibly the same applies to the transfusion treatment of the anemias, although preserved blood appears adequate for the treatment of acute hemorrhage and surgical shock. For these purposes Macdonald and Stephen¹⁹ join me in the belief that the addition of dextrose (modified Rous-Turner) or dextrin (Maisels and Whittaker) to the preservative is advisable as they both appear to preserve erythrocytes better than plain citrate or the preservative advocated by the Moscow Institute of Hematology. Boland, Craig, and Jacobs²⁰ believe that the M.I.H. preservative is advisable for long preservation and the plain citrate for short preservation. With these conclusions I cannot agree. I advise that blood preserved for more than three days, although apparently satisfactory for the treatment of acute hemorrhage and surgical shock, should not be used in the transfusion treatment of acute and chronic infections, and the anemias and hemorrhagic states.*

*An additional advantage in the use of preserved blood may be greater safety from the danger of transfusion syphilis. I have inoculated 10 c.c. of fresh citrated blood with 1 c.c. of a heavy suspension of virulent *Treponema pallidum* (Nichols-Hough strain) from acute testicular syphilomas of rabbits showing approximately 200 treponemes per dark field. A rabbit inoculated at once with 1 c.c. of the citrated-blood-treponeme mixture intratesticularly, as well as rabbits inoculated one and three hours later, developed acute testicular syphilis in about five to six weeks. Rabbits inoculated one, two, seven, fourteen, and twenty-eight days later (the mixture being kept at 4° to 6° C.) escaped testicular infection, and lymph gland transfers to fresh rabbits made six weeks later were negative. The results indicate, therefore, that *Treponema pallidum* in citrated blood may die after twenty-four hours of preservation at 4° to 6° C.

THE RETICULO-ENDOTHELIAL SYSTEM: ITS PHYSIOLOGY AND PATHOLOGY*

CHARLES A. DOAN, M.D., F.A.C.P., COLUMBUS, OHIO

IMMUNITY, as currently conceived in the light of the factual evidence accumulated over the past fifty years, consists in the effective interaction of at least two essential components, the one cellular, the other humoral. With the development of vital dyes by Ehrlich,¹ and the demonstration by Goldmann² of their selective segregation in large phagocytic cells throughout the connective tissues, the foundation was laid for studying the protective role of specialized mammalian cells in the disposition of foreign particulate material, both animate³ and inanimate.⁴ The recent chemical synthesis of azo dye antigens⁵ has now provided histo-immunologists with a crucial link in the chain of objective evidence⁶ required to identify this same system of phagocytic cells as the most probable source of circulating, humoral, immune, antibody globulins.⁷ The really tremendous significance of these cellular constituents to mammalian health and survival, therefore, has been gradually but certainly established. Conversely, the physiologic conservational phagocytic activity of this system of cells may become excessive for one or another of the normal circulating elements, resulting in a variety of constitutional pathologic states, which will be analyzed briefly later. Thus, throughout the modern era of the microscopic study of cellular systems and tissue reactions, which has paralleled closely the evolution of the science of bacterial immunology, *functional* rather than purely morphologic considerations have dominated all researches in this field by necessity as much as by choice.

MORPHOLOGIC AND PHYSIOLOGIC CONSIDERATIONS

The speculative curiosity and academic interest of the embryologist and the histopathologist, nevertheless, through the years have continued to guarantee the accumulation of various morphologic details bearing upon the respective origins and the relationships which the phagocytic cells of the blood and tissues bear to each other, and to the nonphagocytic tissue elements. Suffice it to say here, without reviewing in extenso the variety of opinions and evidence presented elsewhere,^{8, 9} that Aschoff and Kiyono¹⁰ in 1913 very well indicated, and at the same time effectively arbitrated, the two chief divergent hypotheses in the conception and creation of the term "reticulo-endothelial system." By this designation it was implied that the definitive phagocytes of blood and tissues, other than the "microphages" (neutrophilic granulocytes) of Metchnikoff,¹¹ could be derived either from connective tissue reticulum or from specialized endothelial cells, or from both, depending upon location and circumstance, and, perhaps, definition. At the present time only minor modifications or elaborations of this broad func-

*From the Department of Medicine, College of Medicine, Ohio State University, Columbus.

tional generalization may be said to have resulted from the intensive and diversified clinical and experimental investigations carried forward during the intervening years.

Any careful, firsthand, objective study of the problem today with the variety of techniques available will reveal certain, readily verifiable morphologic facts, subject to few exceptions, but susceptible of no little controversial interpretation. Reference to Chart I will suggest a skeleton outline of possible cell relationships within the broader limits of the reticulo-endothelial concept. It reflects one more attempt to "streamline" the consensus of current opinion as the basis for this part of our discussion. At the apex is placed the non-controversial, universally accepted, multipotential, mesenchymal anlagen for all blood and connective tissue elements, from which point of departure all cell relationships and interrelationships and interpretations under consideration must by common consent originate. In the most primitive connective tissues at least three morphologic types of cells may always be differentiated: fat cells, endothelial cells, and reticulum cells.

ROLE OF THE FAT CELL

The lipoblast, forerunner of the widely distributed fat cells of the tissues, arises from undifferentiated perivascular, mesenchymal cells related to the reticulum and entirely distinct from fibroblasts (Maximow, Mallory, Friedrich, Wassermann).

Wells¹² has recently emphasized again the necessity of including adipose tissue within the reticulo-endothelial concept in harmony with the glandlike histologic character of the unfatted fat organs, and in conformity with the evidence that many cells distended with fat are still entirely capable of carrying on other functions. Dogliotti¹³ has shown that both brown and white fat tissue cells may store vital dyes like other reticulo-endothelial derivatives, which process is especially well seen in the depleted fat cells; and Bremer¹⁴ has demonstrated in the thin cytoplasmic ring in the periphery of fat-distended cells, granules of vital dyes suggesting participation by fat tissue in antibody formation. As might be anticipated, the opposite interpretation of such objective observations has been advanced, Chun Chang¹⁵ believing his experimentally altered omental and marrow fat cells in the rabbit to be nothing more or less than macrophages with a predominant fat content. He cites the finding of phagocytized hemosiderin and entire granulocytes in such fat-laden cells as circumstantial evidence of a macrophage origin for all fat cells. Certain it is that monocyte and lipoid-stimulated epithelioid cells of blood and tissues frequently show a special type of progressive fatty metamorphosis, resulting in ultimate cell rupture in tuberculosis associated with caseation.¹⁶ Hausberger¹⁷ has reported the ability of the interscapular fat organs to form fat from carbohydrate by way of glycogen deposit in the fat cells. Sehoenheimer's studies¹⁸ with fat marked with heavy hydrogen showed immediate deposition of most of the food fat in specific adipose tissue, rather than direct metabolic utilization. The capacity of depleted fat cells to take up water, thus becoming extremely hydropic, has been noted in our own studies of experimental marrow hypoplasia in pigeons,¹⁹ and observations by Wassermann²⁰ of hydrosis of distended

fat cells led him to suggest that adipose tissue may play an important role in water metabolism. The truth probably lies somewhere between the extremes of the positions taken by the various investigators; viz., that lipoblasts are more or less differentiated cells of the connective tissues, predominantly equipped to efficiently store and promptly release essential fatty substances in the normal metabolic economy of the mammalian body, and on occasion, under special circumstances, such cells may take in small amounts of other substances; the true macrophage, conversely, participates, if at all, in fat phagocytosis only incidental to fat necrosis and to other pathologic disturbances involving fat metabolism, as for example the xanthomatoses.

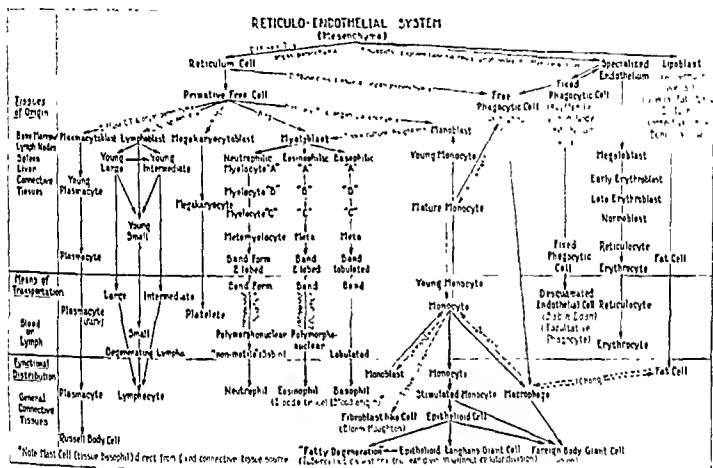

Chart 1.

TISSUE MACROPHAGE

The large highly phagocytic macrophage found in the parenchyma of spleen and bone marrow and scattered throughout the diffuse connective tissues is rarely seen in the circulating blood due to its size and sluggish motility. Such cells divide, giving rise to new, potentially phagocytic units on demand, their ultimate, fixed tissue origin being difficult to determine, being possibly reticulum (Chart 1). They phagocytize large particles of debris, digest whole red and white blood cells, selectively segregate vital dyes, and show intravacuolar reactions to neutral red, with a pH range from 6.8 to 8. Anchored in the sinuses of the liver and presumably deriving from the lining endothelium are functionally and morphologically similar units, the so-called Kupffer cells. In lymph nodes subject to drainage from areas of necrosis or hemorrhage, the sinus endothelium hypertrophies, becomes highly phagocytic, and individual cells may even detach themselves, becoming free and rounded phagocytes.

THE MONOCYTE

On the other hand, always to be found in the circulating blood physiologically are the potentially phagocytic monocytes (large mononuclear or transitional cells of Ehrlich), which when stained supravitaly with neutral red, reveal a more or less definite rosette pattern of small preformed segregation vacuoles, with constant pH.²¹ Their number in the blood is usually a direct reflection of their quantitative, extravascular representation in organs and tissues of the body, and they participate more or less actively in the cellular reaction to a variety of stimuli.²² These blood monocytes appear to arise in the intervascular tissue spaces in association with undifferentiated, fixed reticulum cell hyperplasia, and must undergo a period of development with the elaboration of characteristic mitochondria and specific vacuoles before motility or functional maturity are attained. However, under stress, when engorged with whole blood cells or excessive nonspecific debris, the definitive phagocytes in a given inflammatory area frequently become indistinguishable morphologically in terms of their endothelial or reticular cell origin. The term "macrophage" (big eater) correctly and accurately describes such cells irrespective of their remote derivation.

INTERRELATIONSHIPS OF THE PHAGOCYTIC CELLS OF MAMMALIAN TISSUES

Starting, therefore, ultimately either from specialized fixed endothelium or from fixed reticulum cells with primitive mesenchymal potencies, certain free phagocytic cells arise, showing more or less differentiating criteria with respect to cell size, morphology, staining reaction, degree of motility, intravacuolar pH, segregation capacity, and selectivity. Under various pathologic conditions and during *in vitro* cultivation, these differences may be either accentuated or minimized. Such firmly established and well-documented observations have resulted in two principal divergent interpretations; first, that all morphologic variations reflect simply different phases in the life cycle and/or stage of functional activity of one cell strain; second, that environmental circumstances more or less modify or efface the original identifying criteria of cells with phagocytic potencies arising from two or more sources.

The evidence adduced to date from tissue culture has tended largely to support the first conception. In the earlier studies the survival *in vitro* of living blood or tissue cells was associated almost invariably with extreme vacuolization, much of which was degenerative. With improvements in technique, more particularly the determination of essential nutritional elements and optimum gas concentrations for explanted cells, and with adequate provision for elimination of catabolic products, conditions were rendered more nearly physiologic and interpretations have been correspondingly more readily transferable to *in vivo* phenomena. During recent years in this laboratory, Houghton²³ has directed *in vitro* culture studies toward the better understanding of this problem of the interrelationship of blood and tissue phagocytic cells. The monocyte of the normal blood would seem from these observations to have very considerable powers of survival, multiplication, and adaptation to functional requirements, more certainly than can be demonstrated for circulating lymphocyte, or for any of the granulocytic series of cells. Under these con-

ditions definitive "macrophages" appear, which are indistinguishable from the tissue macrophages and which quite obviously have been derived from the circulating blood monocytes.

Ebert and Florey²⁴ modified the Sandison-Clark chamber technique for the *in vivo* study of the extravascular development of the monocyte in the rabbit's ear. Tissue cells were marked with vital new red, pontamine sky blue, or trypan blue. With the aid of carbon injections, circulating ink-containing "monocytes" were observed to emigrate into the organizing clot on the growing edge of an injured tissue area. However, "though it was thus made certain that the blood monocyte was capable of developing extravascularly into a cell indistinguishable from that frequently called a histiocyte, it was not quite clear that *all* the macrophages present at the developing edge originated from monocytes. It is conceivable that some were due to the mobilization and division of pre-existing tissue histiocytes." While supravital preparations of rabbits' blood stained with neutral red were reported to have been made, no study of the tissue cells under similar conditions is recorded by these investigators. My co-workers and I^{16, 21} have shown that acid diazo dyes in dosages comparable to those used by Ebert and Florey, while prominently identifying the so-called macrophages or histiocytes already in the tissues, are only rarely, if at all, demonstrable within the monocytic derivatives, if the latter are defined and identified by the rosette of vacuoles, revealed by superimposing vital neutral red upon the living tissues in question. Ebert and Florey interpret their data as supporting the monocytic origin of the tissue histiocyte, but in all fairness, a critical review of their evidence is hardly more convincing or conclusive in that direction than many previous studies. Of genuine interest, from the functional standpoint, however, are their observations suggesting that macrophage-ingested erythrocytes may be completely broken down within two hours, and that these same tissue macrophages, containing ingested vaseline, survived, and remained relatively stationary in position and condition within their rabbit ear "chambers" over an eleven-month period.

Reference to Chart 1 again may assist in clarifying the ramifications and probable relationships of those morphologically differentiable cells which contribute ultimately to the group of functionally active phagocytes known descriptively and collectively as macrophages. From fixed endothelium and from fixed reticulum—either directly, or via the lipoblast-fat cell route, or through the monoblast-monocyte-epithelioid maturational development—may be derived definitive units, which become increasingly difficult to recognize in terms of their origin, as maximum, heterogeneous, nonspecific, phagocytic activity obscures all other cytoplasmic criteria. Under physiologic conditions there can be no doubt as to their individual identity and more or less selective functions: the tissue-distributed macrophages of spleen and bone marrow always contain senile red blood cells in their role of conservator of iron to the body, and an occasional identifiable white cell; the Kupffer cells of the liver and the mesenteric lymph node endothelium contain debris salvaged from blood and lymph streams in the normal course of keeping the blood stream free of bacteria and of partially broken down proteins from the gastrointestinal tract; the monocyte retains its rosette of vacuoles, and is fastidious in its selection of only small particulate

debris in contradistinction to the tissue elasmatoocyte or macrophage; and the fat cells clearly limit their activities to the storage of lipoids. True, however, to the universal biologic principle of a common responsibility for community survival when external danger threatens, any or all of these physiologically distinctive units may, under pathologic conditions, become mobilized in a common cause involving the utilization of a common potential phagocytic capacity, and, to a greater or lesser degree, each may be able to contribute to the humoral antibody globulins so essential to adequate cellular defenses. In this connection, Sabin⁶ has pointed out that even the fibroblast may be seen to take up minute amounts of vital dyes or dye antigens when excessive quantities are forced upon the tissues, and that they may contribute their share to the circulating humoral antibodies.

Just as these various cells function more or less selectively in response to specific physiologic demands, thereby assuming certain distinguishing morphologic characteristics, it seems reasonable to assume that under differing pathologic requirements one or other of these units might be able to assume the major role of defense, to be secondarily aided from other areas, if and whenever necessary. Such has been demonstrated to be the case. In tuberculosis the monocyte-epithelioid response appears to be primary;¹⁶ in kala-azar the macrophagic ingestion of *Leishmania donovani* bodies leaves the monocytes of the hamsters relatively unaffected.²⁵ As further studies of pathologic reactions are analyzed on the basis of these cellular concepts, the examples will doubtless be multiplied.

Turning now to other areas where the interrelationships are perhaps less involved, we come to the question of monoblast and myeloblast. Usually under both physiologic and pathologic conditions these stem cells, precursors of their respective cell strains, may be more or less readily differentiated. The criteria are admittedly more readily applied in supravital preparations and Romanowsky stained blood films than in fixed sections. It is in tissue culture, however, that the potential capacities for dedifferentiation have been most strikingly observed. Houghton²³ believes, from his studies of normal human blood, that the myelocytes which appear in his cultures after three to six weeks are not arising from "primitive cells," but from the so-called "monocytes," which gradually lose their more mature characteristics and then begin to elaborate specific granules or to develop vacuoles and phagocytic capacities typical of the macrophage. In cultures of leucemic monocytes there is the uniform appearance of fibroblast-like cells after a few days, unquestionably derived from the monocytic elements; this is in sharp contrast to cultures of lymphatic and myeloid leucemic cells. Houghton's observations would tend to invest the monocyte with the most versatile capacities for response to environmental demands of any of the blood or tissue elements. Aside from this unexpected attribute of specific granule elaboration by the monocyte in cultures, the myeloblast of the normal bone marrow differentiates from parenchymal reticulum cells, develops specific granules, either neutrophilic, eosinophilic, or basophilic in reaction to the Romanowsky stains, and follows the maturational sequence generally recognized.¹⁹

The lymphocyte, with its lack of differentiating characteristics, continues to intrigue the imagination of all cytologists as the most logical "primitive

cell" from which an elaboration of specific cytoplasmic structures or materials may arise. However, as increasingly detailed and careful cytologic and functional studies are applied to lymphocytes in blood, lymph, lymph nodes, and tissues, it becomes ever more evident that this cell has an independent life cycle²⁵ and existence (Chart 1) altogether comparable with those observed for the myeloid and erythroid elements.¹⁹

The plasma cell, while always found in close association with the lymphocyte, physiologically and in chronic inflammatory tissue reactions, would seem to stem back rather directly to the primitive free cell arising from reticulum, and to develop from an immature plasmacytoblast with highly individual mitochondrial characteristics rather than from the differentiated lymphocyte.

The intravasular origin of megaloblast and red blood cell series from fixed, specialized, hematogenic, capillary endothelium in bone marrow²⁷ is indicated on Chart 1 for the sake of completeness, and to suggest the functional relationships of endothelium under differing circumstances, but has no other place in this discussion.

PATHOLOGIC CONSIDERATIONS

Congenital Hemolytic Jaundice.—Directly related to the well-established physiologic phagocytic function of the reticulo-endothelial system for senile, or damaged, or imperfect blood cells would seem to be certain constitutional pathologic states in which an excessive destruction of these same elements is at least one factor contributing to the clinical symptom syndromes. Normal erythrophagocytosis, occurring in the macrophages of spleen, liver, and bone marrow in varying degree in different species, is followed promptly by red blood cell disintegration and by a splitting of the hemoglobin molecule into globin and heme. The latter is further broken down into (1) the iron-free pigment *hematoidin*, which becomes the bilirubin of the plasma in hemolytic jaundice, or is secreted by the hepatic parenchymal cells as bile; and (2) *hemosiderin*, in which form iron remains stored until needed for hemoglobin re-synthesis in the bone marrow. Mann and his associates²⁸ have demonstrated conclusively that the macrophages of spleen and bone marrow, not the stellate cells of the liver, are normally the principal sources of bilirubin, and Kanner²⁹ has reported, and we can confirm, that no histologic alteration in the Kupffer cells of the liver occurs in hemato-genous icterus. Upon these observations may be based the modern approach to the pathologic physiology of human congenital hemolytic icterus. A dominantly inherited constitutional tendency to excessive hemolysis, upon which many environmental factors (pregnancy, trauma, minor infections) may play disastrously, has been clearly established.³⁰ The more active phases of this disease are invariably associated with a directly proportionate degree of splenomegaly, in which excessive parenchymal erythrocyte segregation and phagocytosis may readily be demonstrated. Moreover, splenectomy, when successfully accomplished, and if it includes the removal of all accessory splenic tissue—even though the operation be performed during an acute hemolytic crisis³¹—invariably results in an immediate, complete, and usually permanent remission. Any significance, other than diagnostic, of defective, spherocytic erythrocytogenesis in congenital hemolytic icterus remains unsettled. Haden³² believes spherocytosis to be the congenital prerequisite to increased erythrocyte

fragility, while Dameshek³³ interprets spherocytosis as the end result of hemolysin activity upon mature red blood cells without any inherent marrow defect. The fact that splenectomy is followed by a return not only of red blood cells, but also frequently of thrombocytes and granulocytes, to more nearly normal, highly stable, equilibria, at least suggests that any marrow contribution to this clinical syndrome is dependent upon a more fundamental splenic dysfunction. Farrar, Burnett, and Steigman³⁴ report a patient with hemolytic anemia with hepatic degeneration who responded dramatically to emergency splenectomy although excessive erythrophagocytosis by splenic macrophages was not apparent. An hemolysin was demonstrated in the blood serum before, but not after, removal of the spleen. Thus, at least two possible mechanisms of red blood cell destruction must be attributed to the spleen in hemolytic states; the one, direct phagocytosis by reticulo-endothelial cells, the other, indirect hemolysin elaboration, probably by the same cells.

Thrombocytopenic Purpura.—Reference has been made to the frequency with which a mild thrombocytopenia and granulocytopenia are found secondary to primary splenic anemia.³¹ Either of the former disequilibria may become primary in certain individuals and dominate the clinical and laboratory pictures. There is one type of thrombocytopenic purpura directly related to a normal-sized but pathologic spleen, and dependent upon, either selective abnormal macrophagic destruction of platelets³⁵ or splenic inhibition of marrow megakaryocytic functional efficiency,³⁶ or "thrombocytopen"³⁷ derived from the spleen. In these patients, successful splenectomy is followed by a prompt and maintained return of platelets to the circulation without any recognizable change in number and histologic integrity of marrow megakaryocytes before and after surgery.³⁸ The reticulo-endothelial phagocytes in these spleens probably play a more or less important role in the peripheral destruction of the important platelet elements.

Primary Splenic Granulocytopenia.—Recently a primary granulocytopenic syndrome, with marrow myeloid hyperplasia, splenomegaly without hepatic pathology, and a negative history for drug or bacterial idiosyncrasies, has been described from this clinic.³⁹ Hemolytic erythrocytopenia and/or thrombocytopenia have been either incidental or nonexistent. The clinical manifestations have ranged from acute, through subacute, to chronic, and in each instance splenectomy has resulted in complete recovery. Careful supravital surveys have confirmed in every instance a tremendous excess of highly phagocytic macrophages in the splenic parenchyma, with whole intact granulocytes representing the principal engulfed material; the organs, fixed and sectioned, using ordinary techniques, lost much of the dramatic demonstration of selective phagocytosis seen in the fresh tissues.

Banti's Syndrome.—In Banti's syndrome the splenomegaly found accompanying progressive hepatic cirrhosis of varying etiology⁴⁰ is characteristically associated with a granulopenic leucopenia, which is partially relieved by splenic artery ligation, and completely corrected by splenectomy.⁴¹ Here again the sternal marrow shows no interference with normal hematopoietic activity, and any anemia is usually secondary to occult or obvious gastrointestinal hemor-

rbages. Both leucopenia and moderate thrombocytopenia, on the contrary, are apparently related to an hyperplasia of overactive macrophages in an hypertrophied spleen.

The evidence just presented, viewed in its entirety and in its interlocking and overlapping details, would certainly seem to justify the belief that the physiologic function of reticulo-endothelial phagocytosis by the normal spleen may become pathologically accentuated, either as an inherited or as an acquired trait; and that any or all of the elements arising in the marrow physiologically may be individually or collectively preyed upon to the extent or degree of producing symptoms characteristic of each critical deficit point, respectively. In addition to the usual information, differential and quantitative cell studies of the sternal marrow, together with data obtainable from the adrenalin test, are essential to the critical analysis of the mechanism underlying these several syndromes, and as a basis for determining their therapeutic rationale.

RELATIONSHIP OF THE RETICULO-ENDOTHELIAL SYSTEM TO HUMORAL IMMUNITY

In addition to the observations of selective phagocytic activity on the part of the reticulo-endothelial cells, a great many investigations have been undertaken in the attempt to demonstrate a direct relationship between this cellular system and humoral immunity. Reticulo-endothelial cell blockade with carbon particles or various vital dyes, or extirpation of the spleen, or both, have preceded the administration of a variety of antigens, with the variation in antibody titers, subsequently developed, used to measure the specific sensitivity of the tissue response. Most of the evidence thus accumulated has seemed to indicate the existence of an intimate relationship between the integrity of the reticulo-endothelial system and antibody formation.

When foreign erythrocytes are injected into an animal for the first time, they are promptly removed and destroyed by intracellular phagocytosis; when red blood cells from the same source are again injected after a suitable interval, intravascular, extracellular hemolysis occurs through the action of circulating hemolysins. That the cellular elements originally responsible for the elimination of the foreign red blood cells by phagocytosis should be the most likely source of the newly developed hemolysins is a reasonable assumption. In support of this hypothesis is the almost complete agreement that hemolysin production is interfered with to a greater or lesser degree by reticulo-endothelial blockade.⁴²

Persistent endocrine therapy has been frequently observed to lead to the development of hormone refractoriness. Collip and his collaborators⁴³ have shown that acquired hormone refractoriness is serologically transferable, and certain studies have pointed toward a compensatory hypertrophy of antagonistic endocrine glands as the underlying mechanism.⁴⁴ The extensive and highly suggestive experimental studies reported by Gordon, Kleinberg, and Charipper,⁴⁵ however, seem to link the reticulo-endothelial system to this phenomenon. They found that, while the daily subcutaneous injection of pregnant mare's serum, gonadotropin, caused a maximum ovarian weight increase in normal female rats by the seventeenth day, in parallel tests with splenec-

tomized female rats the initial rate of ovarian increase was twice as fast, and the development of refractoriness was delayed until the twenty-fifth day. By combining splenectomy with trypan blue blockade, hormone refractoriness with resulting regression in ovarian weight was not observed even after fifty-five daily hormone injections. Refractoriness to thyrotropic hormone in normal guinea pigs developed within twenty days, whereas in splenectomized, dye-blockade controls it was delayed for at least fifty days. The effects of splenectomy on the development of testicular hypertrophy in male rats following daily injections of gonadotrophic substance were in accordance with the same law. Gordon and his colleagues argue that since participation of the reticulo-endothelial system seems to be essential for the development of hormone refractoriness, antihormones are true antibody, immunologic adaptations despite their alleged failure to give routine, complement deviating, test tube reactions.

Most convincing, however, in this general area have been the recent cooperative investigations of chemist, immunologist, and cytologist, each utilizing the latest technical approaches to the problem in his own domain. In 1930 Heidelberger and Kendall⁵ synthesized a dark red dye protein, R-salt-azobenzidine-azo-egg albumen, with marked antigenic properties, that showed highly selective phagocytosis by cells of the reticulo-endothelial system.

Preparing a more highly purified antibody than had previously been available, Heidelberger and his associates,⁷ using the ultracentrifuge and determining electrophoretic mobilities, found the molecular weights and electrical phenomena of antibodies to be those characteristic of proteins. This was in conformity with the previously observed invariable association of antibodies with the globulin fractions in serum. Sabin,⁴⁶ it will be remembered, pointed out in her early study of the chick blastoderm, among other things, the liquefaction of some of the angioblastic cells differentiating from the primitive mesenchyme to form the first protein-containing blood plasma. Ranvier⁴⁷ had noted the "shedding of exoplasm" by certain of the larger connective tissue cells in the frog, which led him to designate these elements as clasmatocytes. Supravital preparations of living cells from blood, lymph nodes, spleen, omentum, or peritoneal fluid regularly confirm the fragmentation of cytoplasm. This phenomenon is especially prominent in young lymphocytes, monocytes, and clasmatocytes or macrophages. These observations suggest the mesothelial origin of some, if not all, of the serum proteins; and the increase in fibrinogen and globulin following large doses of India ink and saccharated iron oxide⁸ has been explained on the basis of a stimulation of the tissue phagocytes. Recently Sabin⁶ took the alum precipitate of Heidelberger's dye protein, whose readily visible purplish-red particles had been proved to be of superior antigenic potency,⁷ and followed its physical disposition via various avenues of injection in rabbits. When given intravenously, the resulting antibody titer was higher than when the antigen was introduced by the intradermal, subcutaneous, or intraperitoneal routes, with phagocytosis by local macrophages and by the lymphatic endothelium and free macrophages of the regional lymph nodes only.

The details of this study make fascinating reading, but the evidence as finally interpreted seemed to justify the following conception: the phagocytic endothelium, both vascular and lymphatic, as well as the free macrophages

of the tissues everywhere, are constantly phagocytizing foreign materials which may be divided into two general groups, antigens and nonantigens. These substances are first segregated into the vacuolar organs of digestion of the cell and prepared for diffusion into the cytoplasmic zone of synthesis; the normal food substances ingested are utilized in the formation of normal globulin, but foreign antigenic proteins increase and modify this synthesis of globulin, so that with the shedding of parts of the surface films of such cells, both normal and antibody globulins are carried into the blood plasma. This conforms with the observation of a concomitant increase in both under such circumstances. These cells, during the period in which the modified globulin remains within the cytoplasm, react differently from the normal cell in the presence of additional original antigen, thus relating "sensitization" and "immunization" to different phases of the same mechanism.

The variation in species and individual response to various antigenic substances is readily explained by Sabin's observations. Two distinct steps are necessary for the development of antibodies: first, the phagocytosis and intravacuolar preparation of the antigen for introduction into the cytoplasm proper; and, second, the synthesis of new and modified globulins. Both these phases require time, which would naturally vary with the quantity of antigen available, its relative ease of degradation, and its ability to modify normal globulin synthesis. Furthermore, the units which comprise this phagocytic defense system of the mammalian organism are as diversified in origin and definitive type, and probably, therefore, in functional specificity and efficiency, as are the several units of a modern arm—granulocytes, monocytes, mastocytes, endothelial phagocytes, specialized as in the Kupffer cell and nonspecialized as in the lining cells of the lymph sinuses; and it is probable that each responds differently, quantitatively if not qualitatively, to different antigens and under different environmental circumstances. The various chemotherapeutic agents either assist or prevent clinical recovery in infectious diseases to the extent that they aid or hinder this important cellular mechanism of the body in its phagocytic and antibody-forming functions plus any direct effect they may have on pathogenic bacteria.

These recent studies of Dr. Sabin and her chemical and immunologic collaborators mark an enormous advance in our understanding of the essential mechanism of natural and acquired immunity, yet represent but a logical consummation and final unique demonstration of an hypothesis supported by the gradually accumulated experience of many years.

SUMMARY

In summary, the following points may be accepted as a tentative working basis for present therapeutic applications, and for further exploratory excursions into this absorbing and important phase of medicine: (1) the reticulo-endothelial system represents a functional unit arising from mesenchymal derivatives possessing a common phagocytic capacity; (2) certain morphologic variations associated with a variety of physiologic functional requirements may be recognized; (3) under pathologic conditions and in tissue culture such morphologic criteria may become either accentuated or diminished; (4) when highly stimulated, all phagocytic cells, regardless of the ease of differential

identification under physiologic conditions, tend to assume a common appearance and may be designated by the common descriptive term, macrophage; (5) while originally protective and conservational in functional objectives in the normal body economy, these phagocytic scavengers of the mammalian tissues may assume an excessive selective destructive affinity for any of the normal blood elements, thus precipitating a variety of characteristic clinical syndromes; (6) the spleen is usually the site of the greatest destructive activity, and when the appropriate diagnostic tests have localized the major pathology to this organ, splenectomy is indicated as the rational therapeutic procedure; (7) conclusive evidence of the active participation of the reticulo-endothelial cells in humoral antibody production would now seem to have been obtained; (8) this reaction has both favorable (protective antibodies) and unfavorable (hemolysin production) implications for mammalian survival; (9) a constantly increasing accumulation of carefully controlled factual information is providing an ever broader and more substantial foundation for a more effective manipulation of this important defense unit in the interest of individual health.

THE MECHANISM OF BACTERIAL ALLERGY*

J. BRONFENBRENNER, PH.D., ST. LOUIS, MO.

WHENEVER antigenic substances of foreign origin are brought into contact with inner tissues of animals past the natural barriers, the physiologic behavior of such animals is radically changed: they are rendered allergic (allergy = altered reactivity). In final analysis this alteration consists of an acquisition by the tissues of these animals of a specifically directed increased capacity to immobilize, neutralize, and eventually to eliminate the particular foreign matter if it is subsequently introduced.

While different antigens vary as to their effectiveness in causing the establishment of this altered reactivity, in general the necessary stimulus for altering the reactivity of the exposed tissues (immunogenic = allergenic stimulus) can be produced by the parenteral entry of extremely small amounts of antigens (allergens). Thus, even in the case of antigens possessing an intrinsic toxicity or a capacity to engender infection, this alteration of reactivity can be accomplished by introducing these antigens in amounts below the quanta necessary to cause primary injury (though in practice it is preferable to use for this purpose larger amounts of modified material rendered atoxic or avirulent).

The specificity of this altered response is mediated by antibodies which thus may serve as indices of the past immunogenic (allergenic) experience of a given animal. If the antibodies are produced in sufficient abundance to appear free in the circulation, the blood serum of such animals may serve for a passive transfer of this specific altered reactivity to normal animals.

Besides noting the presence of antibodies in the blood or tissue juices, the state of specifically altered reactivity of the animal can be detected either by observing the response of the animal as a whole (systemic reaction) to systemic reintroduction of the antigen in question, the local inflammatory reaction produced in certain most accessible tissues by the exposure *in situ* (skin, conjunctiva, nasal mucosa), or by exposing excised reactive tissues to contact with antigen *in vitro* (Schultz-Dale reaction).

While the term "allergy" was coined by von Pirquet¹ to denote the totality of this specifically altered reactivity, irrespective of the method by which it is demonstrated, and disregarding the character of the final effect produced in the animal, in current colloquial usage the term "allergy" has been frequently employed more specifically with reference to the inflammatory skin response elicited in previously exposed (immunized = allergic = sensitized) animals by intracutaneous introduction of the antigen (allergen) in question (which presumably causes no such reaction in the skin of normal animals). In

*From the Department of Bacteriology and Immunology, Washington University Medical School, St. Louis.

this narrow sense "bacterial allergy" denotes the skin reaction elicited by bacteria and their products. This reaction is utilized in clinical practice to detect the existence of a specific altered reactivity presumably engendered by previous exposure to the particular bacterial antigen.

Because of certain differences in the general characteristics of skin reactions to certain bacterial antigens as compared with response to other antigens such as soluble proteins, it is currently and erroneously assumed that the mechanism of bacterial allergy is essentially different from that of hypersensitiveness to other antigens. This unwarranted assumption is largely due to the fact that much of the early knowledge concerning bacterial allergy came by way of the study of hypersensitiveness in tuberculosis.

The hypersensitiveness developed as a result of exposure to the tubercle bacillus, however, is not entirely typical of bacterial allergy in general. In some respects it represents an exception in that the exposed animal in addition to producing antibodies (and thus becoming sensitized) to preformed antigens present in the bacillus itself (as in the case of an exposure to other bacterial antigens), develops also sensitivity to some as yet not definitely known product originating within the infected tissue (tubercle). While direct evidence for the existence of this product is not abundant, the experiments of Mc Junkin² (with peritoneal exudates of tuberculous animals) and those of Zinsser and Grinnell³ (in which delayed necrotic tuberculin-like reaction was obtained with products of autolyzed pneumococcus in animals previously sensitized with large amounts of this organism) point in this direction. Moreover, the findings of Dienes⁴ clearly show that delayed inflammatory (tuberculin type) response may be elicited with antigens other than bacterial, notably with egg white (and presumably with other common antigens), provided that on the first exposure the antigen is introduced (directly or indirectly) into a site in which an inflammatory process has been set up. In short, the basic mechanism of allergic response in tuberculosis is not different. It represents merely a modification in some of the details of the reaction due to superimposition of the peculiar properties of the tubercle bacillus and of the pathologic process which it engenders; under suitable conditions this modified type of response can be superimposed on the usual allergic reaction to such typical antigen as egg white.

That the response of hypersensitive animals to bacterial antigens is basically identical with that observed with typical antigen derived from other sources has been shown in some of the earliest studies. Thus Krauss and Doerr found in 1908 that intravenous injection of bacterial extracts into guinea pigs causes typical anaphylaxis and death of sensitized animals⁵ and that the serum of animals sensitized with bacterial vaccines is capable of inducing hypersensitiveness in normal animals, so that such passively sensitized animals respond with anaphylactic shock to a subsequent intravenous injection of homologous bacterial extracts.⁶ More recently, Zinsser and Parker⁷ showed that isolated smooth muscle of either actively or passively sensitized guinea pigs responds with typical contraction when it is exposed *in vitro* to contact with specific bacterial extracts.

Even in the case of hypersensitiveness to antigen of tubercle bacillus these basic responses have been elicited, provided that the complicating factors incident to the complexity of the antigenic structure of the bacillus and of the pathologic process it engenders are eliminated. Thus Enders⁸ produced typical anaphylaxis in guinea pigs by intravenous injection of the soluble specific substance (specific hapten) of this organism both in animals actively sensitized with dead tubercle bacilli and in those passively sensitized with immune rabbit serum. Similarly, instead of a delayed necrotic reaction typical of the response in infected animals, an immediate evanescent wheal and erythema, characteristic of the usual response to ordinary soluble antigens, is elicited when animals sensitized with extracts of ground-up tubercle bacilli receive intracutaneous injection of tuberculin.⁹

It is to be noted, however, that in all the experiments already quoted, the antigenic materials used for sensitizing the animals, and particularly for eliciting the typical immediate response of hypersensitive animals, consisted either of crude bacterial extracts or of separate soluble fractions isolated from the latter. When coarse fragments of bacteria or suspensions of intact organisms are used in place of extracts, the local response of sensitized animals consists of an atypical delayed inflammatory reaction; and when such particulate antigens are introduced intravenously, one may fail to elicit any symptoms whatever if all soluble material has been carefully removed by centrifugation. To elicit typical symptoms analogous to those observed with ordinary soluble proteins (such as egg white, serum, etc.) bacterial antigens must also be present in the state of solution. However, this dependence of the symptomatology of allergic response on degree of dispersion of the antigen is not a particular attribute of bacterial allergy. The failure to elicit typical reactions has been noted with any antigen if it is used in a more or less coarsely particulate state, such as erythrocytes, for instance. That the physical state of antigen is the determining factor is particularly clearly seen in the instance of such common antigens as egg white, which similarly fails to elicit characteristic reactions in sensitized animals if the test injection of this antigen is given in the form of coarse particles (as seen when suspension of particles of collodion coated with egg white are injected instead of a solution of egg white). If this question of the degree of dispersion of antigenic material is kept in mind, it becomes clear that atypical reactions observed with bacterial antigens do not indicate any difference in the basic nature of the reaction and do not justify the separation of bacterial allergy as being due to a different mechanism.

Similarly, the claim that bacterial allergy seems to differ from allergy to soluble proteins in that it may be elicited in certain instances in the absence of demonstrable antibodies, is also invalidated upon adequate analysis. It should be noted that intact bacteria in general possess a relatively low antigenic activity. Even in the case of bacterial extracts, several injections of antigen are required for the production of appreciable concentration of circulating antibodies, as well as for securing effective experimental sensitization. This is most likely due to the fact that bacterial substance, even in extracts, is for the most

part *not* in the state of true solution, and a large part of it is phagocytosed, digested, and thus eliminated from the circulation before it has had opportunity to produce widespread antigenic stimulation upon the body cells necessary for the copious production of antihodies.

On the other hand, small amounts of antigen circulating in the blood even for a relatively short time may be fixed by such tissues as the skin, an organ known to take up very quickly from the circulation many (but not all) substances introduced into it,¹⁰ and produce local antigenic stimulation. It is for this reason that not infrequently the skin test to bacterial protein (as well as to other poor antigens) may be positive, while the blood stream may show so low a concentration of antibody that its demonstration by usual serologic methods may fail altogether. Moreover, similar irregularities can be shown to exist under certain conditions even in the case of ordinary protein antigens. For instance, if a normal guinea pig receives a sensitizing injection of egg white or of horse serum and subsequently is tested by daily intradermal injections of the homologous antigen, the character of the response to intradermal injection will vary as the antibodies are being gradually produced. The skin test performed twenty-four hours after the sensitizing injection will be negative; that is, the animal still fails to react allergically—it behaves like any normal animal. However, on the second or on the third day (while no circulating antibody can as yet be demonstrated), the animal may exhibit a modified skin response—namely, at the sight of injection there will appear a wheal. However, instead of appearing immediately after injection as is the rule when soluble protein is injected into the skin of a fully sensitized animal, there will be a delay of from eight to twenty-four hours. Only after several days (five to seven or more) have elapsed after initial sensitization will the animal respond with a typical evanescent wheal and erythema, appearing within a few minutes after intradermal injection of the antigen; at this time circulating antibodies can usually be found. This occasional failure to demonstrate the circulating antibody (and consequently also the failure to secure a passive transfer with the serum of hypersensitive individuals) does not suffice to justify the claim that this type of hypersensitiveness is independent of antibody. In fact, in many such instances where ordinary methods have failed, it is possible to demonstrate the presence of antibody either by sharpening the methods of detection (such as the use of agglutination of antigen-coated particles instead of attempting to secure precipitation of the antigen directly¹¹) or by securing the antibody from skin extracts or blister fluid.

A particularly important source of confusion in connection with attempts to arrive at the proper correlation between the somewhat aberrant phenomena observed in clinical bacterial allergy and those elicited in hypersensitiveness to relatively simple soluble proteins, is the complexity of physical structure and of the antigenic composition of the bacterial cell. Both when acting as a sensitizing antigen and as a reagent for eliciting the existing state of altered reactivity, bacteria do not act as a single antigen but represent "packages," each containing a variety of independent antigens and haptens. As a result, depending upon the initial portal of entry (and, in final analysis, depending upon the relative rate of disintegration of cells and liberation of independent

antigens), the parenteral introduction of heat-killed suspension of a pure strain of bacteria may result in the production of a variety of antibodies simultaneously or of some at the exclusion of others. Thus, for instance, repeated *intravenous* injection of heat-killed suspension of the smooth variant of pneumococcus of a given type will give rise to type-specific (anticarbohydrate) as well as to species-specific (antiprotein) antibodies, and consequently will bestow upon the skin of the recipient animals the capacity to react to isolated specific carbohydrate derived only from the particular type of pneumococcus, while at the same time it will react to the protein fraction derived from the pneumococcus of any type. The serum of such animals will specifically agglutinate suspensions of this organism and will passively protect mice against infection with homologous type of pneumococcus only.

However, while the specific carbohydrate of these cells is the factor which determines the type specificity of this bacterial antigen, the isolated carbohydrate by itself is devoid of the power to stimulate antibody production unless it is intimately coupled to other constituents, as in the intact bacterial cell. Consequently, intravenous introduction of ground cells, or in any way disintegrated cells, derived from identical cultures fails to stimulate the production of type-specific (anticarbohydrate) antibodies.

Similarly, if the killed suspension of *intact* bacterial cells is introduced repeatedly *into the skin* of normal animals (instead of intravenously as above), such animals also fail to develop type-specific antibodies. Consequently, their serum does not possess the type-specific agglutinins, nor is it capable of conferring passive protection to infection in mice, although the animal (donor of the serum) itself has acquired a degree of resistance to infection not only with homologous, but with any type of pneumococcus. The skin of such animals will fail to react to specific carbohydrate, but will react to the protein fraction derived from pneumococcus of any type.

On the other hand, when bacterial antigens are employed as reagents to elicit the presence of the altered reactivity of the skin, the outcome of such tests frequently may be vitiated, depending upon whether or not the proper antigenic components or the specific haptens are present, and whether they are available in a particular preparation in particulate or in soluble state.

In addition to the above-mentioned constituents, the cell of pneumococcus possesses several other antigenic components. Analogous, though not identical, components are present in all bacterial cells, and not infrequently it happens that some of the constituents of the cells of a given bacterial species are antigenically more or less closely related to the corresponding constituents of the cells of more or less biologically unrelated bacterial species. It is not surprising, therefore, that some of the results of skin tests suggest a relative lack of specificity. Yet with adequate knowledge of the "antigenic spectrum" of the reagents used, these apparently confusing findings may often be adequately interpreted without assuming the existence of a fundamental difference between the respective mechanisms of bacterial and protein allergy. For example, the skin of animals immune to pneumococcus type II will react to extracts of Friedländer type B bacillus, and serum of such animals will protect

normal mice against experimental infection with this organism. This apparently nonspecific phenomenon of bacterial allergy is easily explained by the finding that the specific carbohydrates of these two biologically unrelated organisms are antigenically related. This relationship can be proved by showing that the skin of animals immunized by intravenous introduction of suspensions of Friedländer type B (but not of any other type) bacillus will reciprocally react both in vitro and in vivo with the specific carbohydrate of type II pneumococcus, but not with that of any other type of this organism. Similarly, because *Bacillus proteus* X₁₉ possesses a carbohydrate immunologically related to that present in Rickettsia, the former organism, while utterly unrelated biologically, is routinely employed as a reagent (antigen) in serologic diagnosis of typhus (Weil-Felix reaction).

Furthermore, this complexity of antigenic structure, with all the resulting apparently nonspecific immunologic cross reactivity, is not limited to bacteria, but is found also in the tissues of higher plants and animals. Thus, for instance, the presence of related alcohol-soluble constituents (so-called Forssmann antigen) can be demonstrated by immunologic tests in several unrelated species of bacteria, as well as in corn, beets, turnips, and in certain tissues of chickens, guinea pigs, horses, and in the type A₂ human erythrocytes.

Thus, while this apparent lack of specificity may be confusing, it is not a particular attribute of bacterial allergy, and if not recognized represents a potential source of error in all immunologic reactions with complex antigens. In reality, the apparently aberrant phenomena observed in bacterial allergy (provided all other potential errors* incident to skin-testing are eliminated), far from indicating lack of specificity, on the contrary are the expression of strict specificity which transcends the demarcations of our current classifications.

Still another characteristic which is adduced as a reason for ascribing to bacterial allergy a mechanism distinct from that operating in protein allergy is the lasting effects of desensitization. While specific desensitization is readily accomplished in experimentally sensitized animals, clinical literature is replete with evidence of failure to secure corresponding results in human beings. Moreover, in the case of protein sensitivity in man, in those instances where desensitization is attained, it is less solid (with respect to its intensity) than that exhibited in experimental animals and is of relatively short duration. In contrast to this, while desensitization with bacterial antigens is not more certain of attainment, in cases where it succeeds it is usually found to be more solid and considerably more lasting.

In order to be able to interpret the meaning of these observations, it is necessary first to recall what is the basic mechanism of desensitization in protein anaphylaxis. As the term itself implies, it is generally assumed the failure of desensitized animals to react to injection of antigen is due to inability of tissue cells to anchor the latter because of exhaustion of antibodies

*Such errors as occasioned by differences in age, physiologic condition of the subject, and particularly the physiologic state of the skin (anergy, dermatography); the presence of foci of infection (both specific and unsuspected past or present "undercurrent" infections of subclinical intensity); presence of contaminating unrelated antigens and impairment of specific antigenic reactivity of the reagents which may arise as a result of improper procedures used in their preparation, etc.

at their surface. However, ample evidence indicates that such a concept is incorrect, and consequently the term "desensitization" itself is a misnomer. From the fact that in animals experimentally sensitized to several antigens, repeated injection of one of them reduces the reactivity of these animals to all the other antigens, it is clear that the exhaustion of specific antibodies (even if it should occur) is not the proper explanation. Similar conclusion can be drawn from the observations that no matter how successful, desensitization is never absolute. While "desensitized" animals may fail to react to injection of several times the initially reactive dose of antigen, the injection of still larger amounts will elicit specific response. Furthermore, a comparable degree of refractoriness can be induced in sensitized animals irrespective of the nature of sensitizing antigen (nonspecifically) by parenteral introduction of a great variety of substances both possessing antigenic properties (such as milk, defibrinated autogenous blood, nonspecific bacterial vaccines, etc.) as well as of those devoid of intrinsic immunogenic activity (such as peptone, Bayer 205, lecithin, and in general, substances capable of causing nonspecific "anaphylactoid" reactions). It appears that the degree of effectiveness of this nonspecific refractoriness (desensitization) directly depends upon the degree of systemic or local disturbance evoked by injection. The specific "desensitization" by the introduction of homologous antigen is merely one of the means of producing somewhat analogous disturbance ("colloidoclasia" of Widal), and here again the more intense the reaction resulting from a "desensitizing" injection, the higher is the degree of refractoriness attained. It is for this reason that in animals currently "desensitized" by injection of nearly lethal doses of specific antigen the refractoriness is regularly attained. In human beings we deliberately decrease the dosage (as should be done) in order not to cause any serious disturbance; consequently in order to attain any appreciable degree of refractoriness many such injections are required. The duration of the refractory state so produced directly depends upon the amount of antigen injected to produce it. With bacterial antigens (which are relatively less reactive than soluble proteins) we introduce considerably more reactive material. This is eliminated more slowly and continues to maintain the state of refractoriness through continued combination with antibodies until all antigen is eliminated, when original sensitivity returns just as in the case of hypersensitivity to proteins. It is this residual bacterial antigen which is eliminated very slowly that is responsible for the fact that frequently in chronic infections, or in cases with old incompletely absorbed foci of past infection, the skin tests yield negative findings in spite of the presence of demonstrable antibody.

SUMMARY

The facts brought out in the preceding discussion indicate that the irregularities observed in connection with specific response to intradermal injection of bacterial substrates are not fundamental in nature. They are due largely to the complexity of composition, physical state, and relatively low immunogenic properties of bacterial antigens. The cumulative evidence indicates that the basic mechanism involved in bacterial allergy is identical with that of allergy to simple proteins.

TREATMENT OF ALLERGIC DISORDERS WITH HISTAMINE AND HISTAMINASE*

H. L. ALEXANDER, M.D., ST. LOUIS, MO.

THE essentials of treatment of allergy have not changed much in the last twenty-five years. They depend primarily upon the discovery of the particular foreign substances to which the patient may be hypersensitive. Such a process is usually an involved one and utilizes skin tests, elimination diets, and other forms of environmental control to detect the offending allergen. None of these is consistently dependable, and once the cause of symptoms is discovered, its removal or a defense against it by specific prophylactic injection may by no means be simple. It has, therefore, been the ambition of many to find a way that would circumvent the dependence on a specific immunologic approach. Many therapeutic measures have been introduced for this purpose: injections with colloidal suspensions, bacterial vaccines, glandular substances, x-ray and fever therapy, and a host of others. Among these have been histamine and histaminase.

HISTAMINE

The basis of histamine therapy for allergic disorders is theoretic, and vaguely so. It depends upon the assumption proposed by Dale several years ago that when the particular foreign substance to which man or animal is hypersensitive comes in contact with its specific antibody in the tissue cells, histamine is released. Histamine, in turn, causes smooth muscle spasm and localized edema which are the lesions of anaphylaxis and allergy. Dale's theory has much to support it. Whether it is actually histamine or something akin to it that is released by the tissues is not known. Lewis¹ proposed the term "H-substance" to designate a histamine-like substance.

Although the process by which histamine is elaborated by the tissue cells was unknown, therapy with this substance for allergic disorders was introduced some years ago on the theory that it might act as a type of vaccination, although it had been shown that histamine had no effect in preventing anaphylactic shock in animals. Recently this has been questioned. Nevertheless, histamine was given to patients with bronchial asthma, hay fever, urticaria, and migraine, with indifferent results, and in time this form of therapy was abandoned. In analyzing these early methods of histamine administration, it is noteworthy that injections were given as a rule every few days, which, as will be discussed, may have been the cause of its failure.

During the past three or four years, treatment with histamine has been revived and is receiving considerable support. In contrast to previous experience

*From the Department of Medicine, Washington University, and Barnes Hospital, St. Louis.

with it, two outstanding facts have emerged: namely, its use is limited largely to chronic urticaria, and initial injections are given daily or even twice a day.

Dzinich² was probably the first to demonstrate that cases of chronic urticaria could be markedly benefited by small daily doses of histamine. The same method was successfully used by several investigators in angioneurotic edema and in patients with so-called "cold allergy,"³⁻⁵ in which edema of the skin occurs on exposure to low temperatures. The initial dose is small, 0.01 mg., which may be built up rapidly to 0.3 mg. After two or three weeks, when improvement occurs, injections are given every other day, then twice a week, and finally are discontinued. Individuals vary in their tolerance to histamine, but when symptoms of overdosage, such as flushing, headache, and palpitation, do occur, they are transitory.

Fiessinger and Gajos⁶ claimed success in the treatment of urticaria by introducing histamine into the skin by iontophoresis. This establishes a depot of the drug, which is slowly absorbed. According to Abrahamsou,⁷ histamine introduced in such a way will remain in situ for several days. Alexander and Elliott⁸ were the first to treat urticaria with histamine given intravenously. The method consists in diluting 0.2 mg. of the base with 10 c.c. of physiologic saline and injecting it slowly. It had been demonstrated by Barsonm and Smirk⁹ that there is a direct ratio between the speed of injection and the amount tolerated. When 6.7 γ were injected in two seconds in a normal subject, facial flushing and acceleration of the heart appeared. No further signs were evident when 333.0 γ were given over a period of 9.3 minutes. In treating urticaria the speed of injection should be such that slight facial flushing and feeling of warmth will occur. The second injection, usually of 0.5 mg., is given the following day, and it was surprising to discover the degree of tolerance that could be established. A third dose of 0.7 mg. may be given the next day. As a rule, urticarial wheals diminish after the first or second dose, and itching becomes less. Even when wheals disappear, intravenous treatment should be supplemented by subcutaneous injections. Otherwise symptoms usually recur within a few weeks.

In the treatment of urticaria with histamine a distinction must be made between cases with discrete spontaneous whealing and those with dermatographism where wheals appear only at pressure areas. The latter cases do not respond to such treatment. The only important supplementary measure is the use of theelin in women who develop urticaria at the time of the menopause. This hormone given alone in such cases is not as effective as when combined with histamine treatment.

Recently, Horton¹⁰ described a type of headache occurring usually in older individuals. Symptoms appear particularly at night while recumbent and are relieved on standing. The pain is very severe, but lasts only a brief time, ten to fifteen minutes. It is always on one side of the head, and is accompanied by vasomotor disturbances as flushing and sweating on the side involved. Histamine given subcutaneously will promptly reproduce the syndrome. When administered in small daily doses as in urticaria, these patients experience marked relief. Histamine therapy has likewise been used for migraine, and although its

effect in this disorder has not been encouraging, sufficient cases wherein the drug was given daily have not been reported to evaluate its merit.

Horton¹¹ also described the successful treatment of Ménière's syndrome by the intravenous injection of histamine. There have been no confirmatory reports.

The literature on histamine treatment is vast, for it includes not only its use in allergic syndromes, but also in various skin manifestations, arthritis, gastrointestinal complaints, neuroses, orthopedic conditions, and many other disorders. Chronic urticaria and angioneurotic edema, types of "physical allergy," headaches, and Ménière's syndrome are the only manifestations associated with allergy in which histamine has been used with any measure of success. Although this form of therapy offers considerable promise, its evaluation should be tentative until supported by further confirmatory series of cases.

The mechanism of histamine therapy is far from understood. A significant fact is that the conditions in which it is successful differ from asthma, hay fever, and atopic eczema in that no extrinsic allergens as pollens, foods, etc., are usually identified. This applies to chronic urticaria, which differs from the acute form which is frequently traced to allergens as shellfish, strawberries, or drugs. Likewise in physical allergy, and in the type of headaches described by Horton, which have some resemblance to migraine, specific allergens are not etiologic factors. Such cases, as well as a small proportion of those of bronchial asthma and vasomotor rhinitis in which no external cause can be identified, have been classified as "intrinsic" allergy, which implies that the cause of symptoms originates within instead of without the body. This is believed to be histamine or H-substance, identical or at least similar to that which is released on contact between allergen and antibody in cases of extrinsic allergy. The simplest demonstration of the ability of cells to release H-substance without the involvement of an immunologic mechanism is seen in the wheal that results from stroking the skin of a dermatographic subject. There are doubtless several conditions which initiate the release of histamine by the tissues.

It appears, then, that histamine therapy is of value in certain manifestations of intrinsic allergy, and to be effective it must be given, at least in the beginning, in daily doses. Why histamine should not alleviate symptoms caused by extrinsic allergens which involve an immunologic mechanism is not understood. The necessity for frequent doses likewise is not clear. This is in keeping, however, with certain related facts. One is the demonstration by Grant and his associates¹² that once H-substance is released by cells of the skin there is a short refractory period, probably less than forty-eight hours, when no further H-substance appears. It is possible that histamine given daily may gradually induce such refractoriness. Again, in the treatment of certain physical allergies as, for instance, urticaria due to cold, frequent exposures to increasingly lowered temperatures by means of baths may quickly ameliorate the whealing. Here, too, treatment must be daily to be effective, which suggests the maintenance of a refractory period. In these cases one may soon arrive at a lowered temperature without production of symptoms which before treatment would have caused violent urticaria. This

demonstration, together with the fact that doses of histamine, particularly when given intravenously, may be increased many fold without symptoms, indicates that a tolerance to histamine introduced from without or to H-substance elaborated from within undoubtedly may be built up. Tolerance to histamine so induced bears a close resemblance to the process of immunization, but since neither true antigens nor antibodies are involved, some other mechanism must be implied. Space will not permit discussion of various possibilities, none of which have as yet been proved. There is much, however, to recommend the participation of histaminase which is produced by certain tissues.

HISTAMINASE

In 1930 Best and McHenry¹³ prepared extracts from intestinal mucous membrane, which when incubated with histamine caused its disappearance. They believed the active agent to be a specific enzyme to which they gave the designation "histaminase." Considerable work has been done on the nature of the reaction, which has been found to be an oxidative process and influenced by various factors, particularly the pH of the menstruum and the amount of available oxygen. In vitro several hours are required for complete inactivation of histamine.

There have been only few observations on the action of histaminase in the intact animal. Where experiments are carefully controlled, it appears that histaminase will within two or three hours completely inactivate all the circulating histamine in the blood of the rabbit, which contains a large quantity in contrast to that of other animals. Moreover, in one hour, histaminase has been found to influence greatly the action of histamine on gastric secretion.¹⁴ Recent work, as yet unpublished, shows that histaminase under given conditions has some inhibiting effect on the production of anaphylactic shock in guinea pigs.

The first clinical report of the use of histaminase appeared in 1935, and for the following three years it had considerable vogue in Germany. It was employed in a variety of disorders as ulcerative colitis, gastric and duodenal ulcer, hepatic cirrhosis, "articular" rheumatism, purpura, acne vulgaris, and several allergic manifestations. In most instances the series of cases was small, and although some therapeutic success was claimed, the evaluation of results in no instance was a critical one.

Histaminase was distributed in this country by its manufacturer for clinical trial in allergic disorders in 1938. Theoretically, there is much to recommend it since it has the property of inactivating histamine completely, both in man and in the intact animal. Inasmuch as histamine or H-substance in man is believed to be the active agent that causes the symptoms of both extrinsic and intrinsic allergy, histaminase, if it could be effectively applied to the tissues involved, should be the ideal substance to check the allergic process. Since its activity is well established and since, also, it is virtually nontoxic when taken in large amounts, the problems of dosage and absorption remain to be worked out.

Clinical reports over the past two or three years of the effect of histaminase in allergic disorders are, with the exception of urticaria, not

sufficiently numerous to permit compilation of adequate statistics of combined experience. A review of this literature reveals the complete absence of any serious study of the determination of dosage, and also the frequent lack of careful judgment in the evaluation of results. With few exceptions, cases of bronchial asthma, hay fever, vasomotor rhinitis, atopic eczema, and gastrointestinal allergy treated with histaminase have, at best, been questionably benefited.

In contrast to these poor results, there is an impressive experience with urticaria. Over 150 cases have been reported, and with the exception of one notable series, the percentage of relief has been surprisingly high, despite a great variation in dosage. In the evaluation of any treatment of urticaria, whether acute or chronic, comment has been made that symptoms often disappear spontaneously, as well as from the psychic effect of the administration of a new drug. However, until the introduction of therapy with histamine and histaminase, treatment of chronic urticaria, in particular, was discouraging.

Analysis of reported cases shows that there was a pronounced effect on many patients in whom urticaria had existed several weeks or longer. There are numerous detailed case histories, as well as compilations from a sufficient number of observers, to be substantial. Piness and Miller¹⁵ recently reported the failure of histaminase in 29 patients with urticaria. An analysis of this series shows that their interpretation seems overly severe in that 6 persons were admittedly relieved promptly, and many others secured partial relief. The authors' conservatism is based on the question whether these patients may not have recovered spontaneously. In contrast to this report, a series of 17 cases of urticaria, all of which were at least of several weeks' duration and had proved refractory to usual therapeutic measures, were studied by Laymon and Cumming.¹⁶ Complete relief was secured with histaminase in 10 patients; and in 2 who had the disease for nine months and several years, respectively, the degree of improvement in the one of 50 per cent and of 90 per cent in the other was recorded. The drug had no value in urticaria factitia or atopic dermatitis.

As with chronic urticaria of unknown etiology, other types of skin edema and whealing have been benefited by histaminase. These include angioneurotic edema, skin manifestations of physical allergy, the urticaria of serum sickness and the localized swelling of insulin allergy at the site of injection. With all these considered as a group, 161 cases by 14 observers have been assembled. Several are single case reports; others are statistical evaluations. Seventy-six, or 47.1 per cent, were recorded as having been completely relieved or markedly improved; 31, or 19.3 per cent, showed definite improvement; and 54, or 33.6 per cent, were not benefited.

From this report it appears that the value of histaminase in the treatment of allergic disorders is distinctly limited. By far the most frequent expressions of allergy are bronchial asthma, hay fever, and vasomotor rhinitis, and in these histaminase has seemed to be of very little value. This result is in rather marked contrast to the reported experience with its use in

urticaria and angioneurotic edema, and it is noteworthy that several observers treated various allergic manifestations with histaminase and singled out the latter as giving good response.

A larger number of cases must be studied under controlled conditions before any claim for the value of histaminase can be established. Of particular necessity is investigation to establish proper dosage. There is much evidence to show that earlier preparations of histaminase were unstable. This fact, as well as very inadequate dosages, makes earlier reports unreliable. Although from the published data there is no established ratio between the degree of relief and the amount of histaminase administered, large doses in all probability will be found necessary.

DISCUSSION

Evaluation of the therapeutic worth of histamine and histaminase in allergic disorders must for the present be tentative. From the reported experience a rather striking similarity is found between the clinical effectiveness of each. Neither appears to be of value in the manifestations of extrinsic allergy as asthma and hay fever, where an immunologic mechanism is involved. Both, on the other hand, are effective in urticaria, angioneurotic edema, and physical allergy, the causes of which are intrinsic in origin. This fact strongly suggests that histamine therapy operates through the production of histaminase. That intrinsic allergy responds to it and the extrinsic form does not, leads to the question whether the H-substance released by the one is qualitatively the same as that elaborated on contact between allergen and antibody. (Serum sickness is extrinsic allergy but of a different mechanism than that of asthma and hay fever.) Indeed, the question whether H-substance is really histamine has frequently been raised, and there are indications that the two are not identical. These are problems as yet unanswered which are engaging the attention of several investigators.

CONCLUSION

In reviewing the effectiveness of histamine and of histaminase therapy in various forms of allergy, the results are disappointing, especially in view of many enthusiastic claims to the contrary. If, however, present statistics will be substantiated, a new form of treatment limited to intrinsic allergy, which is by far the more intractable type, may be at hand. This shows sufficient promise to warrant further investigation.

CAPILLARY FACTORS IN PROCESSES OF DISEASE*

VIRGIL H. MOON, M.D., PHILADELPHIA, PA.

ADVANCES in knowledge of capillary physiology have clarified many obscure circulatory phenomena, both normal and pathologic. A brief summary of endothelial function and capillary reactions is essential to a comprehension of these.

The chief function of the blood, that of supplying oxygen and other substances to the tissue cells, is accomplished by diffusion through the endothelium. A mere increase in the arterial blood flow to an organ is not sufficient. The metabolic needs of the cells are served only when the blood is spread upon the surface of the capillary endothelium. Increased metabolic activity requires an increase in the area of this diffusion membrane. The capillary tubes are so finely drawn that within them 1 c.c. of blood is in contact with from 5,000 to 7,000 sq. cm. of endothelial surface (Krogh¹). If one can imagine 16 drops of fluid evenly spread upon 4 or 5 sq. feet of surface, he may sense the physiologic efficiency with which a minimum volume of blood is spread upon a maximum area of the diffusion membrane. The mechanism regulating both the endothelial area and the flow of capillary blood is marvelous in its delicate adaptability.

Each organ and tissue has a supply of capillaries adequate to its maximal circulatory needs. During functional activity tissues require twenty to forty times more blood than during rest. In resting tissues most of the capillaries are contracted and bloodless. Functioning cells consume oxygen and liberate products of metabolism. Capillary endothelium is delicately susceptible to lack of oxygen. The walls relax and the endothelium becomes more permeable whenever moderate anoxia develops. This relaxation allows an increased flow of arterial blood, supplying oxygen and other nutrients. Fresh arterial blood contains a hormonal substance, perhaps of pituitary origin, which causes the capillaries again to contract. This limits the flow of blood until lack of oxygen and/or the accumulation of metabolites again cause relaxation. Thus the local circulatory cycle is repeated at a rate commensurate with the functional activity of the cells. This self-regulating mechanism, shown in Diagram 1, serves a double purpose: it both distributes blood and adjusts the area of diffusion surface—the endothelial wall—to the local nutritional needs of the cells. In the perfect economy of normal circulation, no excess supply and no unfilled demand exist. The supply is adjusted to the demand with delicate accuracy. The reaction of capillary endothelium to lack of oxygen and to products of metabolism explains both functional and reactive hyperemia.

Capillary reactions are of major importance in the physiologic reaction to tissue injury—inflammation. Ebbecke² showed that any kind of mild injury, mechanical, thermal, electric, chemical or toxic, caused the cells to release cyto-

*From the Department of Pathology, Jefferson Medical College, Philadelphia.

plasmic substance. This substance affects the adjacent endothelium, causing an increase in its permeability and leading to dilatation of the capillaries. Lewis and his associates confirmed the observations of Ebbecke. It appears that this response, which is entirely independent of innervation, is physiologic. It initiates the inflammatory reaction which tends toward repair and restoration. The vascular dilatation increases the local blood supply and the permeability allows the escape of plasma into the tissue spaces resulting in local edema. The mechanism by which fibrin is formed locally has been understood for many years, but only recently was it shown³ that cellular substance is chemotropic for leucocytes. These responses explain satisfactorily the mechanism of local acute inflammation.

Abnormal Capillary Reactions.—Three instances of hyperemia, functional, reactive, and inflammatory, occur by virtue of the sensitivity of endothelium to alterations in physiologic conditions. That same quality of sensitivity gives origin to abnormal circulatory phenomena. Heidenhain,⁴ some fifty years ago, noted that commercial peptone would produce a decline in blood pressure accompanied by an increased flow of lymph when given intravenously to dogs. He found that extracts of various marine animals and of normal tissues, as liver, pancreas, mucosa, muscle, and others, produced the same effects. He noted in such experiments that both the volume and the protein content of the lymph were increased and that the plasma volume of the blood was decreased—a change now designated by the term *hemoconcentration*. His observation that the maximum flow of lymph coincided with the period of minimum blood pressure is significant. He stated that concentration of the blood was characteristic of the effects of these “lymphagogues,” and attributed those effects to endothelial secretory activity.

After the lapse of half a century, the full significance of Heidenhain's observations becomes apparent. The theory of endothelial secretory activity was not confirmed (Drinker and Field⁵). The increased flow of lymph, its high protein content, the declining blood pressure, the decreased plasma volume, and the hemoconcentration result from leakage of plasma through endothelium rendered abnormally permeable by the effects of the agents used. Many other substances have been shown to produce the effects described. These include certain poisons of vegetable origin, diphtheria toxin, tuberculin and other bacterial products, foreign proteins and products of protein cleavage, sepsin, histamine, bile and cholic salts, venoms, urethane and other drugs, chemicals, and poisons.

The agents mentioned, and many others not listed, have one property in common: that of producing relaxation and increased permeability of capillary endothelium. If this effect is sufficiently widespread, it causes disturbance of the systemic circulation accompanied by a characteristic clinical syndrome and by equally characteristic morphologic changes in the viscera. The latter consist of dilatation and engorgement of capillaries and venules, occasional petechial hemorrhages resulting from endothelial dissolution, stasis evidenced by masses of closely packed corpuscles in the minute vessels, edema of soft tissues, and acute granular degeneration of parenchymatous organs.

A circulatory deficiency arises if the effects described are extensive. The sequestration of blood in dilated capillaries and venules reduces the *effective* blood volume, while leakage of fluid from the blood into the tissue spaces lowers the *actual* blood volume. This tends to produce a disparity between the volume of blood and the volume capacity of the vascular system, the effects of which resemble somewhat those resulting from extensive hemorrhage. Much confusion has resulted from this resemblance. The two conditions may be differentiated, excepting when they coexist in the same individual, by noting that hemoconcentration is present in the former while the opposite change, hemodilution, develops after hemorrhages.

NORMAL CAPILLARY REACTION

Diagram 1.—The sequence of capillary reactions incident to functional activity in the tissues.

Incipient disparity between the volume of blood and the volume capacity of the vascular bed is compensated for a time by physiologic reactions. Impulses, probably originating in the carotid sinus, activate the sympatho-adrenal system. The discharge of adrenalin into the circulation stimulates the myocardium, mobilizes glucose from the liver, contracts the peripheral arteries, and causes the discharge of reserve blood from the spleen and other reservoirs. So long as this compensation is adequate, there is no ominous decline in the arterial blood pressure, but the latter is maintained at the expense of volume flow. When finally the mechanism of compensation becomes inadequate, the blood pressure declines progressively and the circulatory deficiency is manifested clinically.

Prostration is evident; the patient is profoundly depressed, weak, and restless. The pulse is rapid, feeble, and of small volume. The extremities are cold and the body temperature is low. The face is drawn, ashen or livid in color, anxious in expression, and moist with cold sweat. The eyes are sunken and surrounded by bluish rings, producing the classical "Hippocratic facies." Thirst is incessant, but attempts to relieve it are ineffective because of vomiting. The fluid vomited is often in excess of that swallowed and contains small brown flocculi. Perspiration is profuse, and there may be diarrhea. The respirations are shallow and interspersed with deep sighs. The blood pressure declines progressively. Urination is scanty or suppressed. Consciousness is retained until finally there is loss of sensitivity, of responsiveness to stimuli and reflexes. Unconsciousness or coma precedes death.

The clinical syndrome just described is accompanied by an equally characteristic group of departures from physiologic constants. These are a reduced total and effective blood volume; a reduced minute volume cardiac output and volume flow of arterial blood; hemoconcentration, increased nonprotein nitro-

gen, glucose, and potassium content of the blood; reduced alkaline reserve, chloride and oxygen content, and delayed coagulability of the blood. An increased flow of lymph from the thoracic duct is an early and constant feature.

Hemoconcentration.—This term is used to designate a rapid or sudden increase in the ratio of erythrocytes to plasma per unit volume of blood. It may be detected readily by variations in hematocrit readings, in the erythrocytic count, the hemoglobin content, or in the specific gravity of the whole blood. Variations in the latter occur in a narrower range and hence are less useful as a clinical test than variations in the red blood cell or hemoglobin content of the blood.

Diagram 2.—Showing a volumetric comparison of normal blood with that present in shock and that resulting from hemorrhage. If normal blood (first column) becomes concentrated 40 per cent, it will have the composition shown in the second column. Seven cubic centimeters of such concentrated blood will contain the same volume of corpuscles (third column) as 10 c.c. of normal blood, 3 c.c. having been lost. In shock with hemoconcentration of 40 per cent, the normal blood has lost 30 per cent of its total volume and 50 per cent of its plasma volume. The fourth column illustrates the hemodilution which occurs when the corpuscles have been reduced by hemorrhages to 40 per cent of the normal.

Hemoconcentration, shown in Diagram 2, is a highly significant feature in the pathologic physiology of shock. Medical literature contains numerous allusions to it but, until recently,⁶ there has appeared no analysis of its relationship to capillary physiology and to circulatory failure. A survey of the recorded observations indicates that the blood regularly becomes concentrated when circulatory failure of capillary origin occurs. This results from loss of plasma volume incident to leakage of fluid into the tissue spaces, due to abnormal permeability of the endothelium. It is integrally related to the increased flow of lymph discussed in a previous section and to the development of edema considered below. It appears that these phenomena occur whenever and wherever the endothelium in an extensive visceral area is damaged. Any type of injury to endothelium renders it abnormally permeable to plasma (Landis⁷).

An extensive increase in the permeability of capillaries deranges the mechanism of water balance and absorption. The mechanism which governs the movement of fluid between the blood and the tissues depends upon the action of several factors, including capillary blood pressure, osmotic pressure, electrolytic concentrations, hormonal substances, and others. But the presence of a normal semipermeable membrane, the endothelium, is absolutely essential to the action

of these forces in preserving a physiologic relationship between intravascular and extravascular fluids. So long as the endothelium is able to perform its part in the maintenance of fluid balance, no hemoconcentration occurs. A serious change in the permeability of the endothelium deranges vitally the mechanism of both water balance and absorption.

This derangement is shown clinically by unmistakable signs. The peripheral tissues are relaxed, inelastic, and have a doughy consistency which suggests dehydration. Vomiting and thirst are incessant, but fluids given by mouth, by rectum, or by hypodermoclysis, are not absorbed into the circulation. Underhill and others⁸ showed that animals about to die of shock resulting from burns of the skin may be injected subcutaneously with lethal doses of strychnine without effect. Normal controls, similarly injected, died from the effects of the strychnine before the burned animals died of shock. Such observations and experiments indicate that the mechanism both of water balance and absorption is seriously deranged when capillary atony has developed extensively or when this type of circulatory deficiency is present. Loss of fluid by vomiting, diarrhea, and perspiration cannot be replaced normally under such conditions. Marked dehydration both of the tissues and of the blood may result from inability of the endothelium to function as a semipermeable membrane.

Abnormal permeability of endothelium is an important cause for edema. It has been shown⁹ that pulmonary edema may be produced experimentally with ease and certainty by injecting any of the numerous agents which have the property of increasing endothelial permeability. Edema resulted regularly when such agents were given in amount sufficient to affect the circulation but not sufficient to cause immediate death. The edema fluid has a high protein content, approximating that of plasma, and is found in the visceral soft tissues and serous cavities. It is rarely found in peripheral tissues. The mechanism of this type of edema is integral with that of shock. It occurs regularly when this condition develops gradually and when death is delayed for several hours.

Pathologic Physiology of Shock.—The type of circulatory disturbance under consideration occurs frequently under diverse clinical conditions, and may be produced experimentally by a wide variety of agents. The mechanism by which the circulatory function is disturbed has been presented diagrammatically in previous articles (see *Note* at end of paper). This diagram is essential to complete the present discussion.

It is seen that a wide variety of clinical and experimental conditions may cause capillary atony and may thereby give rise to circulatory deficiency of capillary origin. I have included under clinical conditions only those with which I have had personal experience. These presented the clinical picture of shock or circulatory collapse, and the post-mortem findings were those regularly found after death by shock. Also under experimental conditions, only those agents have been listed which we have used experimentally. In each instance these agents produced progressive circulatory deficiency accompanied by hemoconcentration and by congestive visceral changes which are characteristic of circulatory failure of capillary origin. Undoubtedly many other conditions, both clinical and experimental, should be added to those listed.

A highly important feature in the mechanism of shock is the fact that lack of oxygen, independent of other conditions, will cause endothelial permeability (Krogh, Ebbecke, Lewis, Landis). This fact introduces a self-perpetuating quality, causing the mechanism to operate as a vicious circle. Hence the circulatory deficiency, unless effectively interrupted in its earlier stages, progresses and leads to irreversible changes.

It is evident from Diagram 3 that the same type of circulatory disturbance may originate primarily from decreased blood volume, decreased volume flow, or from any condition which decreases the supply of oxygen to the tissues below physiologic limits. Under these conditions, lack of oxygen leads to capillary atony and thereby initiates the operation of the same vicious circle.

SUMMARY

It has been shown that capillary endothelium serves indispensable functions under normal physiologic conditions. These include local capillary hyperemia incident to functional activity of tissue cells, inflammatory hyperemia in response to cellular injury, the processes of diffusion and osmosis both in the distribution of useful substances and in the elimination of wastes. Not the least important function of the endothelial membrane has to do with the mechanism of water balance.

The performance of these functions requires that endothelium be delicately sensitive to oxygen tension, to the presence of metabolites and cytoplasmic substances. This very sensitivity renders endothelium a highly vulnerable structure. Its essential quality of semipermeability and its normal tonus are readily affected by diverse agents. These include lack of oxygen, the presence of metabolites in abnormal concentration, products of tissue injury and protein cleavage, bacterial proteins and toxins, venoms, and various drugs, chemicals, and poisons.

The effects of these and similar agents may cause abnormal permeability of a large area of endothelium. This produces a characteristic clinical syndrome of circulatory disturbance, usually called shock or collapse, accompanied by an equally characteristic group of physiologic disorders. The visceral changes seen at necropsy are those indicative of capillary damage. Hemoconcentration is an associated phenomenon which is highly valuable in the recognition of this syndrome in its early stages.

The action of many drugs, chemicals, and poisons is due in part to their effects upon endothelium. It appears that pharmacologic and toxicologic interpretations may need revision to include the effects of many agents upon capillary endothelium.

The self-perpetuating quality of this type of circulatory deficiency makes early recognition essential to successful management. Hemoconcentration is a more useful index than a decline in arterial blood pressure. The former occurs early and is detectable during the incipient stages, while the latter is a sign that the mechanism of compensation has failed.

Efforts to combat shock will be directed logically toward the removal of the cause, toward the restoration of the lost blood volume and capillary tonus, and toward relieving anoxia.

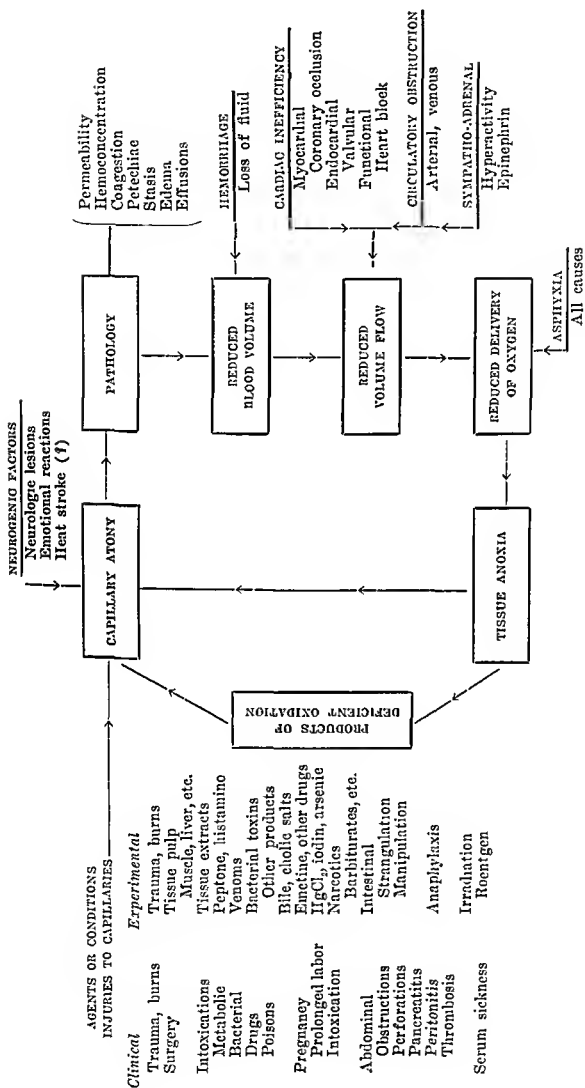

Diagram 3.—The relationship of various factors in the pathologic physiology of shock. The reciprocal effects of capillary atony and tissue anoxia give this mechanism the self-perpetuating quality of a vicious circle.

Unless the condition that caused the circulatory deficiency is relieved, any efforts to restore circulatory efficiency will be useless. Transfusions of plasma or serum are more suitable than whole blood, because they relieve the hemoconcentration by supplying the same type of fluid which was lost. There is physiologic evidence that *one* function of the adrenal cortical hormone is the maintenance of endothelial tonus. Hence the use of cortical extract during the incipient stages of shock is logical. Recent reports of its use in experimental and in clinical shock indicate beneficial effects. The inhalation of oxygen may retard the progress of the circulatory deficiency, since anoxia supplies the self-perpetuating quality in the mechanism of shock.

POSSIBLE SIGNIFICANCE OF THE INHIBITORY EFFECT OF FEVER ON ANAPHYLACTIC PHENOMENA*

*"Fever is a mighty engine which Nature brings
into the world for the conquest of her enemies."*

—Sydenham (1624-1689)

PAUL DE KRUIF, PH.D., HOLLAND, MICH., AND WALTER M. SIMPSON, M.D.,†
DAYTON, OHIO

WHEN Dr. Warren T. Vaughan, Editor of this JOURNAL, invited us to prepare a paper for the special issue commemorating the twenty-fifth anniversary of its founding by his father, our beloved teacher, Dr. Victor Clarence Vaughan, it occurred to us that we should select a subject in which our interest was first aroused by his researches and teachings. This subject is anaphylaxis. Our interest in this field was revived and augmented by certain observations made in the course of studies on artificial fever therapy during the past nine years.

We have, in general, concentrated our fever studies upon those diseases in which investigation had already shown fever—intercurrent, or by inoculation, or by physical means—to have a favorable effect. In our experience these are syphilis, gonococcic infections, chorea, and other manifestations of the rheumatic state, brucellosis, and certain forms of infectious arthritis. Despite the wide variety and disparity of known or alleged etiologic agents, and the absence of any uniformity in the manifestations of these diseases, it is now generally admitted that fever has a beneficial influence on all of them. Many theories have been advanced in an attempt to explain these favorable effects of high body temperatures. Most observers admit, however, that the therapeutic effect of fever rests on an entirely empirical basis.

A generation ago most physicians regarded fever as an alarming manifestation of disease. Antipyretic drugs were widely employed. The past ten years have witnessed a revolution in the concept of the role of fever. It is now known that it is one of Nature's most important weapons of defense. The failure to discover a rational explanation of the defensive action of fever is unfortunate. The acceptance of its beneficial effects has been inhibited by their mystery. Knowledge of the mechanism by which fever acts would not only hasten its wider acceptance as a therapeutic agency, but would also promote further researches toward possible wider therapeutic applications.

There is no doubt that the dangers and the uncertainty of control of fever in the past have maintained the empiricism from which the use of fever has not yet been freed. Medical literature is replete with citations of the beneficial influence of intercurrent infections accompanied by sustained high fever on such

*From the Kettering Institute for Medical Research, Miami Valley Hospital, Dayton.

diseases as chorea, asthma, paresis, and gonorrhea. But it was not until the development of safe and controllable physical methods of producing fever artificially that a scientific tool became available to study the effects of high body temperatures per se. Now the first step toward penetrating beneath empiricism could be taken since the toxic effects of invading organisms present in intercurrent infections were absent.

I. CLINICAL OBSERVATIONS ON THE EFFECT OF HIGH BODY TEMPERATURES ON CERTAIN SENSITIZATION PHENOMENA

(a) *Arsenic Sensitization in Therapy of Syphilis.*—During the first three years (1931-1934) of our experimental studies on the treatment of syphilis by combined artificial fever and chemotherapy,¹⁻⁵ we became gradually aware of the fact that there was an absence of the anticipated proportion of sensitization reactions to arsenical compounds. In time we were forced to the conclusion that fever in some way suppresses such arsenic sensitiveness, and we began to experiment with injections of arsenical compounds during artificial fever into syphilitic patients known to be extremely sensitive to arsenic.

Such a trial appeared to be justified in a young man with primary syphilis who developed severe generalized exfoliative dermatitis following the second injection of neoarsphenamine, ten days after the appearance of a penile chancre.⁴ Because of this patient's marked idiosyncrasy to arsenic, no chemotherapy was combined with the first four fever treatments. The exfoliative lesions disappeared after the third fever treatment. Before the fifth fever treatment was given, the patient was tested with 1/1,000 Gm. of neoarsphenamine. Two days later exfoliation again developed. At the beginning of the fifth fever treatment, when the rectal temperature reached 105° F. (40.6° C.), a similar quantity (1/1,000 Gm.) of neoarsphenamine was injected intravenously. This injection was not followed by exfoliative dermatitis.

During succeeding fever sessions 0.1 Gm. injections of bismarsen were given when the rectal temperature reached 105° F. (40.6° C.). Dermatitis did not develop. Because of this patient's extreme sensitiveness to arsenic, when it was given without the protection of fever, the usual follow-up course of chemotherapy alone was omitted.

Despite the small total quantity of arsenic given in combination with artificial fever, this patient's blood and spinal fluid reactions, strongly positive before fever therapy was instituted, were reversed to negative, and have remained so for four years. Since 1935 it has become our routine practice to treat all patients, referred to us because their arsenic sensitiveness rendered them untreatable by orthodox chemotherapy, with full adult doses of arsenicals under the protection of artificial fever.

Encouraged by these observations on the protective function of fever in suppressing arsenical reactions, we were led to initiate experimental studies designed to shorten greatly the treatment time of early syphilis. Preliminary observations appear to justify the hope that by combining large doses of arsenic and bismuth with one or two long fever sessions, it may be possible to reduce the minimum treatment time from eighteen months to one or two days.

(b) *Artificial Fever Therapy of Chorea and Other Manifestations of the Rheumatic State.*—From 1930 to 1935, in a field apparently far removed from

that of arsenic sensitivity, many workers were making empirical observations on the effect of fever upon a human disease condition of which the mechanism is allergic, or, more specifically, anaphylactic. This is the rheumatic state.

It is generally agreed that the outlook for patients suffering from Sydenham's chorea has improved remarkably during the past ten years. The experience of many workers with various forms of fever therapy, first introduced by Sutton and Dodge⁶ in 1930, indicates that it may be possible not only to abolish the distressing choreatic symptoms, but also to influence favorably other more specifically rheumatic manifestations. We do not here maintain that chorea is invariably the result of rheumatic activity, yet it is generally so regarded when it is accompanied by migratory polyarthritis, and especially by carditis.

All these rheumatic exacerbations are favorably influenced to a greater or less extent by fever. There is no longer doubt that the common denominator of the variety of antirheumatic agencies—such as triple-typhoid vaccine, sterile milk injections, inoculation with relapsing fever—is the production of sustained high body temperatures. Today the various fever-producing inoculations have largely given way to the safer and more accurately controllable artificial fever by physical means.

The notable clinical improvement in rheumatic carditis observed by a number of workers⁷⁻¹¹ is confirmed by marked trends toward normal of heart function, as revealed by accompanying electrocardiographic, roentgenographic, and cardiovascular functional studies. Furthermore, it has been reported by Dunn and Simmons⁹ that the high erythrocyte sedimentation rates, so characteristic of rheumatic activity and of subclinical rheumatic smoldering, are reduced toward normal by artificial fever treatment. These observers believe, from the clinical improvement in carditis and the return toward normal of the laboratory findings (white blood cell counts and erythrocyte sedimentation rates), that most rheumatic patients terminate their active disease more rapidly when treated with artificial fever than when treated with bed rest and large doses of salicylates. They feel that by shortening the period of the rheumatic cardiac exacerbations they are able to minimize the accumulating cardiac damage to rheumatic sufferers.

These findings, confirmed by our own experience,¹² suggest a link between the effect of high body temperatures upon arsenic sensitivity on the one hand, and upon the rheumatic state on the other. For the observations of many workers, beginning with Weintraud¹³ and culminating with the brilliant researches of Coburn during the past ten years, indicate that rheumatism is essentially an anaphylactic condition. During this ten-year period the work of Coburn has brought an enormous number of facts to the support of his original view¹⁴ that certain "effective" strains of the hemolytic streptococcus are causal agents of rheumatic fever, but operate in a different manner, in a pathogenetic sense, from any microbial agents so far known.

As happily and succinctly put by Collis,¹⁵ a great deal of evidence has now accumulated to support the theory that rheumatic disease is caused by an antigen-antibody reaction occurring in certain people born with the rheumatic diathesis or in those who acquire it.

If the various rheumatic insults are, then, expressions of what may be termed "micro-anaphylactic shocks" in mesodermal tissues, is it not possible that the hitherto empirical observations of the favorable effect of high body temperatures upon the various rheumatic exacerbations (chorca, migrating polyarthritis, carditis) may have a rational explanation?

In sum, is it not conceivable that body temperatures, raised to a certain level and maintained there, may not in some way disrupt or nullify the noxious antigen-antibody reaction responsible for rheumatic damage?

(c) *Effect of Artificial Fever on Intrinsic Intractable Asthma and Other Allergic States.*—The age-old observation that the advent of an intercurrent febrile disease, such as scarlet fever, erysipelas, or pneumonia, often resulted in temporary remission or improvement of chronic intractable asthma led Feinberg and his associates¹⁶ to treat with artificial fever a group of 42 patients with intrinsic, intractable asthma. All had failed to respond to accepted modern therapy. Of 35 patients, the result of whose treatment could be ascertained, 51 per cent had complete remission, varying from several days to nine and one-half months, while an additional 39 per cent were appreciably improved. Similarly, favorable responses have been reported by Sheldon,¹⁷ Metz,¹¹ Bennett,¹⁰ Brodribb,¹⁸ Cook,¹⁹ and ourselves.

There is also suggestive evidence that artificial fever therapy exerts a favorable influence upon certain patients suffering from seasonal hay fever, chronic urticaria, and chronic eczema.^{16, 20}

II. INHIBITION OF CLASSICAL ANAPHYLACTIC SHOCK IN GUINEA PIGS BY HIGH BODY TEMPERATURES

By 1936 it had become clear to us that it might be possible to integrate these widely disparate and scattered observations of the inhibitory effect of fever upon the phenomena of arsenic sensitivity, rheumatism, allergic asthma, hay fever, and eczema. In short, if these various disease phenomena are in essence anaphylactic, and if they are more or less controlled and suppressed by fever, then the induction of suitably high temperatures in sensitized experimental animals should inhibit anaphylactic shock phenomena that would otherwise certainly result when the specific antigen was introduced in an effective concentration into their veins.

We laid plans for this crucial integrating experiment in 1936, but pressure of other work delayed putting these plans into experimental action. Meanwhile, Goldman,²¹ of the University of Cincinnati (one of the 29 institutions collaborating with the Kettering Institute for Medical Research in our fever therapy research project), published observations on the inhibitory effect of high body temperatures in still another field remote from those already mentioned. He demonstrated an inhibitory effect of very high fever (108° to 112° F.; 42.2° to 44.4° C.) upon experimental sensitization of guinea pigs to turpentine.

In the discussion of Goldman's paper (read before the Second Annual Meeting of the Society for Investigative Dermatology at St. Louis, Mo., May 16, 1939) I. Arthur Mirsky, together with P. Wassermann, who were associated with Goldman in his fever-turpentine studies, reported their attempt to find some definite mechanism in explanation of his observations. These workers found

that a series of guinea pigs, sensitized to horse serum, and subsequently febrile to temperatures of 109°-110° F. (42.8° to 43° C.), failed to respond with anaphylactic shock when injected intracardially with doses of horse serum that called out typical anaphylactic shock in nonfebrile, sensitized control guinea pigs. These experiments appeared to vindicate our hypothesis that high body temperatures do indeed suppress the classical anaphylactic shock of guinea pigs.

During the past year, in collaboration with R. Gottschall and C. C. Young at Michigan State Health Department Laboratories, Lansing, we have been able to launch a detailed experimental analysis of our hypothesis. In the first place, we were concerned with the extremely high temperatures employed by Goldman, Mirsky, and Wassermann. Such temperatures are not compatible with life in man. Furthermore, clinical observations on suppression of anaphylactic phenomena by fever were based upon temperature ranges which were administered with safety and relative comfort to human beings.

Only by using such temperatures in our experiments on the possible inhibiting action of fever upon classical anaphylaxis, would this crucial animal experiment have significance in integrating the hitherto empirical observations on the favorable influence of fever upon several unrelated human disease conditions.

Preliminary observations, accumulated during our experimental studies now being conducted at Lansing, Mich., leave little doubt that suppression of anaphylactic shock in guinea pigs does occur in the temperature ranges ordinarily employed in fever therapy of human beings.

In these experiments diligent efforts are being made to eliminate error by the use of guinea pigs of pure genetic strain, and by employment of instruments of precision in recording temperatures. The details of these studies will be made the subject of a later communication.

SUMMARY AND CONCLUSIONS

1. The lack of any rational explanation for the favorable influence of fever upon several unrelated disease states stimulated us to search for some basic underlying mechanism for the therapeutic action of fever.
2. The common denominator in the favorable effect of fever in such clinically different conditions as sensitiveness to arsenic, chorea, and other manifestations of the rheumatic state, and asthma and other allergic phenomena, appears to be the inhibition of anaphylaxis.
3. It is suggested that the phenomenon of inhibition of classical anaphylaxis in the guinea pig by body temperatures at levels safely employed in fever therapy of human beings may provide a crucial experimental explanation of these hitherto empirical therapeutic effects.

DEVELOPMENT OF NEW ORGANIC CHEMICALS FOR THERAPEUTIC USE

F. F. BLICKE, PH.D., ANN ARBOR, MICH.

A COMPARISON of the various substances used as medicaments about 1500 B.C., as disclosed in the Eber's papyrus, with those mentioned in three editions of the London Pharmacopoeia, which appeared during the years 1618 and 1766, reveals the fact that practically no progress was made in the field of therapeutic agents for over three thousand years. In contrast to this era of stagnation, the discoveries made during the last fifty years are truly astonishing.

It is difficult to conceive of any development which has been of greater benefit to the human race than that which has taken place in synthetic drugs, and it should not be forgotten that this progress could never have been made without the growth and vast accumulation of data in sciences such as chemistry, physics, bacteriology, and biology.

It seems impossible to devise a rigid, sharply defined classification of synthetic, organic therapeutic agents. Probably the most satisfactory arrangement is one in which the various medicaments are grouped in accordance with their medicinal use. Each major group may then be divided into subgroups on the basis of some characteristic feature in their chemical structure. It will be noticed that the greatest variations in structure are to be found in substances which possess similar therapeutic properties and that compounds of analogous structure sometimes exhibit very different types of physiologic activity.

General Anesthetics.—Ether was used first in surgery in 1842 and chloroform was introduced five years later. Seventy-six years passed before another anesthetic of practical value was discovered, although during this time constant improvement was made in the method of administration of the two drugs. In 1923 ethylene was adopted, followed by avertin (β, β, β -trichloroethyl alcohol), cyclopropane, and vinethene (divinyl oxide). These newer anesthetics possess certain undeniable advantages, but the fact that some of them, especially ethylene and cyclopropane, form very explosive mixtures with oxygen limits their use.

Local Anesthetics.—It was discovered, soon after its introduction in 1905, that procaine (novocain) can be used as a cocaine substitute most effectively and advantageously for infiltration anesthesia. However, for surface anesthesia it proved to be greatly inferior to the plant drug. To some extent this disadvantage has been overcome by the synthesis of products which, although of the procaine type, differ somewhat from the latter substance in structure; some of these are much better surface anesthetics than procaine.

So far, all attempts to obtain a local anesthetic which will produce constriction of the capillaries, and thus make the concomitant use of a vasoconstrictor unnecessary, have been unsuccessful.

* NC_6H_{12} is the 2-methyl-1-piperidyl radical.

Other local anesthetics which should be mentioned are psicaine, psicaine-new, nupercaine, diothane, apothesine, and phenacaine.

Although their low water-insolubility makes them unsuitable for injection, compounds such as anesthesin, butesin, and orthoform are of considerable value for topical application.

Hypnotics.—Most of the hypnotics which are widely used at the present time are amides, a type which was introduced many years ago. Among these we find the substituted acetamides, neuronal, neodorm, and novonal; the acylureas, carbromal, bromural, and sedormid, and especially cyclic amides of the barbituric acid series. Very few new compounds of the acetamide or urea groups have appeared on the market, but year after year new representatives of the barbituric acid series have been introduced until at present more than twenty-four of these products are available.

DERIVATIVES OF BARBITURIC ACID

Formula I

	1	2	5	(5, 5)
Evipala	CH_3-	$-\text{CH}_3$	$\begin{array}{c} \text{CH}-\text{CH}_2 \\ \text{C} \quad \text{CH}_2 \\ \text{CH}_2-\text{CH}_2 \\ \text{CH}_2-\text{CH}_2 \end{array}$	methyl, cyclohexenyl
Barbital ^b	H	$-\text{CH}_2\text{CH}_3$	$-\text{CH}_2\text{CH}_3$	ethyl, ethyl
Neonal	H	$-\text{CH}_2\text{CH}_3$	$-\text{CH}_2\text{CH}_2\text{CH}_2\text{CH}_3$	ethyl, butyl
Amytal	H	$-\text{CH}_2\text{CH}_3$	$-\text{CH}_2\text{CH}_2\text{CH}(\text{CH}_3)_2$	ethyl, isoamyl
Phanodorn		$-\text{CH}_2\text{CH}_3$	$\begin{array}{c} \text{CH}-\text{CH}_2 \\ \text{C} \quad \text{CH}_2 \\ \text{CH}_2-\text{CH}_2 \\ \text{CH}_2-\text{CH}_2 \end{array}$	ethyl, cyclohexenyl
Phenobarbital ^c	H	$-\text{CH}_2\text{CH}_3$	$-\text{C}_6\text{H}_5$	ethyl, phenyl
Mebaral ^d	CH_3-	$-\text{CH}_2\text{CH}_3$	$-\text{C}_6\text{H}_5$	ethyl, phenyl
Alurate	H	$-\text{CH}(\text{CH}_3)_2$	$-\text{CH}_2\text{CH}=\text{CH}_2$	isopropyl, allyl
Nostal	H	$-\text{CH}(\text{CH}_3)_2$	$-\text{CH}_2\text{CBr}=\text{CH}_2$	isopropyl, β -bromoallyl
Dial	H	$-\text{CH}_2\text{CH}=\text{CH}_2$	$-\text{CH}_2\text{CH}=\text{CH}_2$	allyl, allyl
Sandoptal	H	$-\text{CH}_2\text{CH}(\text{CH}_3)_2$	$-\text{CH}_2\text{CH}=\text{CH}_2$	isobutyl, allyl
Pernoston	H	$-\text{CH}(\text{CH}_3)_2$	$-\text{CH}_2\text{CBr}=\text{CH}_2$	sec.-butyl, β -bromoallyl

Formula II

Evipal soluble	CH ₃ -	NaO—	—CH ₃	$ \begin{array}{c} \text{CH} - \text{CH}_2 \\ \diagup \quad \diagdown \\ -\text{C} \quad \text{CH}_2 \\ \diagdown \quad \diagup \\ \text{CH}_2 - \text{CH}_2 \end{array} $	methyl, cyclohexenyl
Medinal*	H	NaO—	—CH ₂ CH ₂	—CH ₂ CH ₂	ethyl, ethyl

Dormaphen	H	—OMgO—	—CH ₂ CH ₂	—C ₆ H ₅	ethyl, phenyl
Sodium alurate	H	NaO—	—CH(CH ₃) ₂	—CH ₂ CH=CH ₂	isopropyl, allyl
Cyclopal sodium	H	NaO—	—CH ₂ CH=CH ₂	$ \begin{array}{c} \text{CH} = \text{CH} \\ \diagdown \quad \diagup \\ -\text{CH} \quad \text{CH}_2 \\ \quad \quad \\ \quad \quad \text{CH}_2 \end{array} $	allyl, cyclopentenyl
Seconal	H	NaO—	—CH(CH ₃)CH ₂ · CH ₂ CH ₂	—CH ₂ CH=CH ₂	1-methylbutyl, allyl
Sigmoidal	H	NaO—	—CH(CH ₃)CH ₂ · CH ₂ CH ₂	—CH ₂ CB ₂ =CH ₂	1-methylbutyl, β-bromo-allyl

(a) Another name is cyclural; (b) veronal; (c) luminal; (d) prominal; (e) veronal sodium, soluble barbitol.

Because of the variety of hypnotics which can now be obtained, the physician has available drugs which are so mild in their effect that they may be classed more properly as sedatives; hypnotics which act very rapidly and others with delayed action; drugs which act over a short or a long period of time; and, finally, soluble products which, after intravenous injection, produce relaxation and narcosis sufficient for major surgery.

Antispasmodics.—During the last ten years more than five hundred compounds have been synthesized and examined pharmacologically in the hope that a product might be found which would be more effective than the naturally occurring antispasmodics atropine and papaverine. The following compounds have appeared on the market: novatropine, syntropan, trasentin, dolantin, eupaverin, perparin, new-paverin, octin, sestron and cyverine hydrochloride; those introduced most recently are cyverine hydrochloride and dolantin. The first four compounds resemble atropine to the extent that they are basic esters; the others, like papaverine, are amines. In general, the activity of the synthetic antispasmodics has been most pronounced in cases of spasms in the gastrointestinal tract. The antispasmodic is still to be discovered which will relieve spasms of both musculotropic and neurotropic character in all types of smooth musculature.

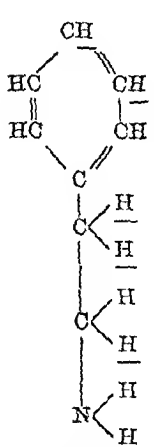

Compounds Which Stimulate Cell Proliferation.—The fact that maggots (*Lucilia sericata*) can be employed effectively to remove necrotic tissue and prevent bacterial putrefaction is well known. In earlier times the comfrey root was used to promote healing of wounds. Some years ago it was found

that allantoin, which stimulates the growth of epithelial tissue, is present in maggot excretions as well as in the comfrey plant.

A number of compounds which differ greatly from one another in chemical structure have been found to act similarly to allantoin, for example, thioercol, thioglycerol, urea, and certain azo dyes. The manner in which these compounds promote tissue growth is not known definitely but an important factor in their beneficial effect seems to be the solvent action on necrotic debris which some of them exhibit.

Pressor Agents.—The prevailing tendency to prepare and substitute synthetic drugs for those obtained from natural sources is illustrated again in the case of pressor agents which are listed below. All of the products may be regarded as derivatives of β -phenylethylamine.

DERIVATIVES OF β -PHENYLETHYLAMINE

	I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII
	H	H	H	NH ₂	OH	OH	OH	H	OH	OH	OH	OH
	H	H	H	H	H	H	H	OH	OH	OH	OH	OH
	H	H	H	H	H	H	H	H	H	H	H	O
	H	OH	OH	OH	H	H	OH	OH	H	OH	OH	
	H	H	H	H	H	H	H	H	H	H	H	H
	CH ₃	CH ₃	CH ₃	CH ₃	H	CH ₃	H	H	H	H	CH ₃	H
	H	H	H	H	H	H	H	H	H	H	H	H
	H	H	CH ₃	CH ₃	H	H	CH ₃	CH ₃	CH ₃	CH ₃	H	CH ₃

β -Phenylethyl-amine

I Benzedrine

II Propadrine

III Ephedrine

IV Ephetonal

V Tyramine

VI Paredrine

VII Synephrin

VIII Neosynephrin

IX Epinine

X Epinephrine (Adrenaline)*

XI Cobefrin (Corbasil)

XII Kephirin

*These naturally occurring drugs can all be manufactured by synthetic processes, and tyramine is obtained entirely in this manner. Whether market supplies of epinephrine and ephedrine are synthesized or extracted from natural products depends upon the current relative costs of the two processes.

Because of all the factors involved—stability of the drug in aqueous solution, effectiveness when administered orally, degree to which blood pressure is affected, compatibility with local anesthetics, volatility and individual idiosyncrasy—a wide selection of pressor agents would seem advantageous.

Diagnostic Agents.—Like so many other discoveries which have originated from purely academic research, that of phenolphthalein, made in 1880, has proved to be of considerable significance to medicine. Its importance as an indicator was recognized almost at once, but it was not until about twenty years later that its valuable laxative property was discovered. After another twenty

years had passed, it was found that a sulfur analog, phenolsulfonephthalein, is eliminated completely from a healthy individual, after intramuscular or intravenous injection, in a remarkably short time; delayed elimination is an indication of kidney dysfunction. Halogen derivatives of phenolphthalein—chloro, bromo, and iodo—are used for such purposes as roentgenologic examination of the gall bladder and as a test of liver function. Fluorescein, closely related to phenolphthalein in chemical structure, finds application as a diagnostic agent in ophthalmology.

Several iodated pyridine compounds are available for intravenous pyelography.

Since the use of the synthetic products discussed above has made exploratory surgical operations unnecessary in many instances, they represent discoveries which have been of very decided advantage to both the physician and the patient.

Diuretics and Laxatives.—During the search for antisypilitics among organic derivatives of mercury, it was discovered that certain representatives of this group are strong diuretics. Several of these mercury diuretics have already been used for a number of years. Merbaphen (novasurol) and salyrgan (mersalyl) are administered intravenously, and mercurin is administered rectally.

Laxatives which represent a single synthetic product of definitely established structure are very few in number. In addition to phenolphthalein, the oldest and best known member of this group, there is istizin (1, 8-dihydroxyanthraquinone) and isacen, an oxindole derivative.

Vasodilators.—Two outstanding effects produced by choline are a lowering of blood pressure and the promotion of gastric and intestinal peristalsis. It has been found that the activity of the compound is increased to a very great degree if certain structural changes are made in the molecule. Modifications of choline which have been found to be valuable drugs for a variety of conditions are acetylcholine chloride, acetyl- β -methylcholine chloride, doryl, and prostigmin.

Analgesics.—Although antipyrine, one of the oldest synthetic drugs, and aminopyrine (pyramidon) are very useful analgesics and antipyretics, they often fail to afford relief from severe pain. Consequently, the physician is still dependent on morphine and certain of its derivatives, the objectionable features of which are too well known to require mention. It seems very probable that if the carefully planned research program of a group of investigators in this country, begun about ten years ago, is continued, a satisfactory synthetic morphine substitute, free from such properties as tolerance and addiction, will be discovered.

The introduction of the synthetic product, dilaudid, indicates that some progress has already been made.

Stimulants for Circulation and Respiration.—There have been very interesting developments in the search for synthetic compounds which would be not only more reliable but which would lack the undesirable properties of naturally

occurring drugs such as strychnine, camphor, caffeine, epinephrine, and digitalis. Among the synthetic representatives in this group are nikethamide (coramine), homocamfin (cyclosal), metrazol (cardiazol), and neospiran.

Germicides.—One of the many difficulties encountered by the investigator searching for more active germicides is the lack of a quantitative method of evaluation by means of which their effectiveness can be determined under clinical conditions. Products which laboratory tests have shown to be of merit often fail to prove satisfactory when they are applied in medical practice.

The "universal germicide" seems to be as far from attainment as the philosopher's stone, and we have practically no knowledge with regard to the mechanism of germicidal activity. However, a definite advance has been made by the recognition that all germicides tend to be specific in their activity and that their ability to kill or retard the growth of microorganisms is dependent on a certain environment. To a considerable extent successful prophylaxis or treatment of an infection must depend upon the proper selection of a germicide and a recognition of the various factors involved in its use.

Organometallic compounds which contain mercury continue to find favor as bacteriostatic agents. Proprietary drugs of this type include mercurochrome, metaphen, meroxyl, mercurophen, merthiolate, sulfomerthiolate, merphenyl nitrate, and mercesin. Any opinion which may have been held that such products must be complex in structure in order to be effective has been disproved by the discovery of the activity of such simple compounds as basic phenylmercuric nitrate and 2-hydroxyphenylmercuric chloride.

A number of other organic derivatives of mercury find use as anti-syphilitics and diuretics.

Azochloramid is a product which belongs to the chloramine group, and zephiran is the first example of an organic germicide of the ammonium type.

Although it has been known for a long time that the phenol coefficient is increased to a great degree by the introduction of halogen or an alkyl group into a phenolic substance, many years passed before practical use was made of phenols which contained both halogen and alkyl radicals, for example, chlorothymol and a wide variety of other chloroalkylphenols.

The discovery that mandelic acid and sulfanilamide are effective germicides in the urinary tract is of great significance.

CHEMOTHERAPEUTIC AGENTS

Anthelmintics.—Since its introduction in 1921, carbon tetrachloride has been used to treat many millions of human beings for hookworm. In some respects tetrachloroethylene seems to be a better drug. Later, the use of hexylresoreinol was advocated and has been given extensive trial. Gentian violet medicinal, suggested for pinworms in 1938, has been used with considerable success. No effective chemotherapeutic agent is known for trichinosis or filariasis.

Trypanocides.—Three drugs of outstanding merit in the treatment of trypanosomiasis are tryparsamide, orsanine, and germanin (Bayer-205).

The complex urea derivative, germanin, introduced about 1920, produces most beneficial effects in African sleeping sickness. It is an example not only of a very brilliant achievement in the field of synthetic drugs, but also of one of the most baffling problems relative to the relationship between chemical structure and therapeutic activity. It is impossible to understand just how the presence of a methyl group can affect in any profound manner the physical, chemical, or pharmacologic properties of a molecule as large as that of germanin ($C_{51}H_{34}O_{23}N_6S_6Na_6$). Nevertheless, the removal of one of the two methyl radicals present in this substance or a shift in its position renders the product almost inactive.

Spirocheticides.—More than eight thousand organic derivatives of arsenic have been prepared but only about twelve of these have found extensive application as medicaments. To the short list of widely used spirocheticides—arsphenamine (salvarsan), neoarsphenamine, sulfarsphenamine, and silver arsphenamine—there has been added, recently, mapharsen. Although this latter substance was known many years ago as “arsenoxide,” its valuable therapeutic properties were not established until 1934.

The massive dose arsenotherapy of syphilis by the intravenous drip method, which has been introduced quite recently, has aroused great interest.

Antimalarial Compounds.—In spite of numerous investigations made in the hope that more effective drugs might be discovered, the quinoline compound plasmochin and the acridine derivative atabrin still remain the most valuable adjuvants to quinine in the treatment of malaria. Progress in this field is made especially difficult due to the fact that all known medicaments exhibit a selective action, that is, their effectiveness varies enormously, depending upon the species, strain, and phase of the parasite.

Drugs for Acute Bacterial Infections.—The efficacy of sulfanilamide, introduced in 1936, in infections due to streptococci, meningococci, and gonococci has been definitely established. In spite of the unparalleled success of this drug, thousands of other sulfur-containing products have been prepared and tested in the hope that new substances would be discovered which would lack its many undesirable by- and after-effects and by means of which the range of therapeutic usefulness could be extended. At present there seems to be little doubt about the value of sulfapyridine (M. and B. 693, Dagenan) in the treatment of pneumococcal infections; sulfathiazole seems to be of definite value for staphylococcal infections.

The forerunners of sulfanilamide, the red dye prontosil and the soluble dye prontosil soluble (neoprontosil), still find application.

Two arsenicals used extensively for the treatment of amoebiasis are ecarbarson and acetarson (stovarsol), while the antimony compound stibosan is employed to combat visceral leishmaniasis.

The elucidation of the structures of many vitamins and hormones and the discovery of processes by means of which they can be prepared in the laboratory, have opened a new field for synthetic work. In some instances, study of these structures has supplied clues which have enabled the chemist to prepare active products which are much simpler in structure than the naturally occurring

substances. It seems not improbable that in the future some of these synthetic products will find favor as therapeutic agents because of such factors as the relative ease with which they can be manufactured, greater stability, and certain unique properties not possessed by the natural vitamins and hormones. Possibilities in this direction are illustrated by compounds such as diethylstilbestrol, diiodothyronine, and certain analogs of vitamin K₁.

Of necessity, the selection of drugs discussed in this article is arbitrary. The mention of a product is not intended to imply recommendation nor does its omission denote lack of therapeutic merit.

THE SEROLOGY OF SYPHILIS*

REUBEN L. KAHN, Sc.D., ANN ARBOR, MICH.

I. INTRODUCTION

THE serology of syphilis has a number of anomalies. It is interrelated with the immunology of syphilis, but it is also interrelated with biologic changes in the absence of syphilis. Serologic tests may employ spirochetal antigens, but they actually employ extracts of normal tissue as antigens. Serologic tests in infections other than syphilis are limited in the degree of sensitivity by the respective infections, as, for example, the agglutination test in typhoid fever, but serologic tests in syphilis may be so improvised as to show a degree of sensitivity not at all limited by this disease. Serologic tests in infections other than syphilis generally consist of but few technical diagnostic procedures, while the number of technical procedures of serodiagnostic tests for syphilis is legion. In addition, syphilis may be manifested by many clinical signs and symptoms occurring in other diseases or by no clinical signs and symptoms, a situation which often makes the serologic test the deciding factor in establishing the diagnosis.

The many varied aspects of the serology of syphilis and the importance of serologic tests in diagnosis make it understandable why we have evaluation committees and serologic surveys; why one laboratory employs one test and another perhaps five; why one believes that test A is better than test B and another, that test B is better than A; why the serology of syphilis, approaching forty years of existence, is still in as controversial a stage as it ever has been.

Yet, the serology of syphilis is beginning to enter a highly promising era. Evidence is accumulating that positive serologic reactions are divisible into two distinct types which can be differentiated in the laboratory: one type being a manifestation of syphilis and the other, unrelated to this disease. Perhaps in this differentiation lies the promise of making serologic tests true diagnostic agents in syphilis.

II. SEROLOGY IN RELATION TO IMMUNOLOGY OF SYPHILIS

Becoming Inoculated With the Treponema pallidum (Spirocheta pallida).—

It is well known that when man becomes inoculated with the *T. pallidum* he shows no signs or symptoms for a considerable period, extending from several weeks to several months. This situation is what might be expected. Man lacks immunity to the *T. pallidum*. To lack immunity to microorganisms is to lack the capability of localizing or fixing the microorganisms in the area in the skin or mucous membrane where they gain entry and of preventing them from invading the blood stream. Absence of this localizing capacity means absence

*From the Clinical Laboratories, University Hospital, University of Michigan.

of a local inflammatory reaction.¹ Also, the entry of microorganisms into the blood stream is apparently not disturbing to a nonimmune host. The result is that the invaded host is not cognizant of the infection.

In the case of the spirochetes of syphilis, the likelihood is that the non-specific localizing capability of the skin and mucous membrane for these microorganisms plays some role in the establishment of the infection. If the spirochetes are few in number and of low virulence, and this localizing capability is sufficient to hold them fixed in the area of entry, they may ultimately be destroyed locally. In most instances, while there may be some nonspecific localization of the spirochetes in the area of entry, this localization is undoubtedly insufficient to prevent them from finding their way into the blood stream. The localization in all probability leads to the formation of a disseminating focus of the spirochetes, a focus from which fresh microorganisms may enter the blood stream and replace those which are unable to survive in this medium. Disseminating foci are undoubtedly established also in the adjoining lymph glands. Thus do the spirochetes establish a strong foothold in the body.

As the spirochetes and their antigenic constituents come in contact with the tissue cells, they gradually bring about immune changes in them. Theoretically, we might expect to note the appearance of antibodies in about ten days or two weeks after the spirochetes gain entry into the body. These are the periods in which antibodies begin to be noted after the injection of an antigenic agent into an animal. In syphilis, however, the continued presence of the spirochetes in the blood stream may tend to delay antibody production. Generally, antibody production begins at a rapid rate as soon as the antigenic agent begins to disappear from the blood stream. Then again, antibodies produced at a time when the antigenic agent circulates in the blood stream may result in antibody-antigen union in vivo, thus reducing the detectable number of antibodies.

The Primary Lesion—A Manifestation of a Certain Degree of Immunity.—Absence of detectable antibodies in the blood stream does not of course mean absence of immunity. The first visible sign of the beginning of the development of immunity in syphilis is the primary lesion. This lesion is a localized one and, in the relationship between a host and microorganisms, a host must possess some specific immunity to keep a lesion produced by the microorganisms localized. Furthermore, in experiments with rabbits carried out in this laboratory in which protein antigens were employed,² it was possible to produce spontaneous ulcerative lesions in the skin, simulating the primary lesions of syphilis in human beings, only when the animals possessed a given degree of immunity.

These experiments can be carried out with relative ease. Rabbits are immunized to horse serum by weekly injections of, let us say, 0.1 c.c. per kilogram of body weight, administered by any route. A week after the fifth or sixth immunizing dose, the rabbits are injected intracutaneously with varying amounts of horse serum. These are so graduated as to cause local inflammatory reactions of varying intensity, as well as reactions so mild as to be invisible. To illustrate: 0.1 c.c. of undiluted serum and of 1:10, 1:100, 1:1,000, 1:10,000 and 1:100,000 dilutions of serum with salt solution are injected intracutaneously. Twenty-four hours later it may be found that the areas in which the undiluted

serum and the 1:10 and 1:100 dilutions had been injected show local inflammatory reactions of varying intensity, while the areas in which the 1:1,000, 1:10,000 and 1:100,000 dilutions had been injected appear normal.

The rabbits are now injected intravenously with a relative excess of horse serum, such as 20 c.c. or more. Soon after the intravenous injection it will be noted that the local skin areas in which the 0.1 c.c. quantities of the varying dilutions of horse serum had been introduced, show a distinct change. The three areas in which the undiluted serum and the 1:10 and 1:100 dilutions of the serum had been introduced and which show varying degrees of inflammation, first become purplish black, then black, especially in the centers of the inflammatory areas. The two areas in which the 1:1,000 and 1:10,000 dilutions of serum had been introduced and which showed no signs of inflammation, now also appear purplish black or black. The last area in which a 1:100,000 dilution of the serum had been introduced shows no change. Should the intravenous injections be repeated daily, the black areas will undergo visible tissue destruction and ulcer formation.

The degree of tissue necrotic flare-ups in preformed specific inflammatory areas in immunized animals, following the intravenous injection of antigen, varies with different rabbits. Some show marked tissue necrotic changes and some mild changes under the same experimental conditions.

In a broad sense, it may be said that tissue necrotic changes in a preformed specific inflammatory area, or in an area in which antigen had been injected in so small an amount as not to call forth visible inflammation, are dependent upon: (a) the degree of immunity of the host, (b) the amount of antigen introduced in the area, and (c) the concentration of the antigen in the blood stream. Similarly, it is believed that the formation of the primary lesion in syphilis (interpreted as a tissue necrotic change in a preformed invisible inflammatory area) is dependent upon the same three conditions. If any of these conditions do not conform to quantitative requirements, it is believed that chancre formation will not take place.

Serologic Reactions During Primary Stage.—The fact that antibodies are not detected by means of serodiagnostic tests at the time of the appearance of the chancre is of interest. In the case of the protein-immunized rabbits considered, a high precipitin titer was shown by them previous to the intravenous injection. Immediately following this injection, the precipitin titer became negative, indicating the disappearance of the antibodies from the circulation. At the time when the rabbits began to show the necrotic lesions within the preformed inflammatory areas, the titer was still either negative or very low. This relative absence of antibodies is believed to be due to antigen-antibody union *in vivo*.

It is likely that the absence of antibodies during the early primary stage is also due to antigen-antibody union *in vivo*. The appearance of the chancre is dependent upon a relatively high concentration of spirochetal antigen in the blood stream. In the presence of a high concentration of antigen, any antibodies that might be present might combine with the antigen *in vivo*, thus leading to seronegative reactions.

The intensity of the serologic reaction in primary syphilis may thus be dependent upon the relationship between the quantities of spirochetal antigen and of antibody present in the blood stream. In the early primary stage, the quantity of antigen probably exceeds the quantity of antibody in the blood stream, while in the later primary stage, the quantity of antibody undoubtedly exceeds the quantity of antigen. In the later stage, one notes definite evidence of immunity of the host against the spirochetes. The primary ulcer had teemed with spirochetes only a short while previously. Now spirochetes are difficult to find and the ulcer is undergoing spontaneous healing. This fact must mean that the host is developing substances destructive to the spirochetes; that it is gaining the upper hand, so to speak, over these microorganisms. Hence, an increase in the antibody titer at this time is to be expected.

It was stated that one of the requirements for the formation of the primary lesion is the presence of spirochetal antigen in sufficient concentration in the blood stream. The question may arise as to what is the relationship between the presence of antigen in the blood stream and the change to tissue necrosis in a preformed specific inflammatory lesion. The probability is that the circulating antigen is attracted to the inflammatory lesion. The basis of this attraction is not fully understood. It is known that a circulating dye tends to accumulate in a nonspecific inflammatory lesion.³ The likelihood is that circulating antigen will accumulate in a specific inflammatory lesion to a far greater extent than a dye. Inflammatory tissue probably possesses marked anchoring or localizing powers for specific antigen. If this view is accepted, then circulating spirochetes would be drawn to the focus of their entry which, although invisible to the naked eye, must be inflammatory. As the spirochetes accumulate in this focus the mild inflammatory reaction changes to a tissue necrotic reaction. This change is based on a principle in immunity emphasized elsewhere;² namely, when free antigen accumulates in a specific inflammatory area, this area undergoes tissue necrosis. Free antigen seems to interfere with the inflammatory process, the blood vessels apparently become filled with thrombi, and with the cutting off of the blood supply, death of tissue is the natural sequel.

Serologic Reactions During Secondary Stage.—Turning to the secondary stage of syphilis, the relationship between the serology and immunology of this stage is also of interest. Serologic reactions are almost invariably positive during this stage. The reason for this, in our opinion, lies in the role of the skin and mucous membranes in immunity. It was shown in our laboratory⁴ that an outstanding feature of the response of the tissues in immunity is the fact that the skin possesses a far greater attractive force for specific antigen than do other tissues. In the case of rabbits immunized with protein antigens, it was found that the skin possesses an anchoring or localizing power for the antigen from ten to fifteen times greater than that possessed by some of the other tissues, such as skeletal muscle. Unpublished experiments carried out by Stellwagen⁵ in our hospital indicate that the surface mucous membranes also possess this high localizing power for antigen. It is, therefore, likely that, as the immunity of the host approaches a given height at the beginning

of the secondary stage, the immunity of the skin and mucous membranes becomes highly intensified. The cutaneous tissue thus possessing a particularly marked attractive force for the spirochetes at this time, it might be expected that, as these microorganisms circulate in the blood stream, they are localized in large numbers in this tissue. This localization would in turn cause many spirochetes to be withdrawn from the circulation—a step which would result in an increase in the antibody titer and in positive serologic reactions.

Serologic Reactions During Other Stages of Syphilis.—In a broad sense, there are three situations in syphilis in which serologic reactions might be negative: (a) when antibodies are not yet formed, (b) when there is an excess of spirochetal antigen in the circulation, and (c) when spirochetal activity has become so quiescent as not to stimulate antibody production.

Little need be said about negative serologic reactions during the incubation period in syphilis before the formation of antibodies. All infections have a similar seronegative period. Negative serologic reactions resulting from an excess of spirochetes or spirochetal antigen in the circulation are in all probability not uncommon in syphilis. Such reactions during the early primary stage, already considered, are assumed to be due to an excess of circulating spirochetal antigen. These reactions are common in precocious malignant syphilis in which the host is literally overwhelmed with spirochetes. Indeed, it can be stated as a principle in immunity that antibody production is disturbed when a host is overwhelmed with an antigenic agent.

Negative reactions may also occur in marked syphilitic flare-ups when large quantities of spirochetal antigen are suddenly thrown into circulation. A syphilitic flare-up generally tends to stimulate antibody production, but the presence of spirochetal antigen in the circulation may lead to antigen-antibody union *in vivo*. When, therefore, the amount of antigen in the circulation is excessive, the antibodies may temporarily disappear from the circulation, undoubtedly due to antigen-antibody union.

Negative serologic reactions during spirochetal quiescence are also what might be expected. Antibody production depends on the antigenic stimulus of the body cells. As the antigenic stimulus is removed, the production of antibodies ceases. Antibodies will continue to circulate in the blood stream for days or weeks after their production has ceased. Sooner or later, however, serologic reactions are bound to become negative as a result of spirochetal quiescence.

Now and then a patient may give negative serologic reactions in the presence of old syphilitic lesions. This situation may be met with when spirochetal activity and destruction of tissue had occurred some time previously. To illustrate: A patient has an aortic aneurysm of syphilitic origin. The processes which led to the formation of the aneurysm may be arbitrarily divided into two steps: (1) an attack of syphilitic aortitis, during which the elastic tissue within the inflammatory area of the aortic wall was destroyed and replaced by fibrous tissue, and (2) the slow and steady expansion of the

fibrous area into a tumorlike mass. It is clear that while the spirochetes had been active during the first step of aneurysm formation, they are not necessarily active during the second step. Inactivity, in turn, means little or no liberation of spirochetal antigen and, hence, little or no stimulus to antibody production. The same statement applies to a perforated nasal septum and to other old destructive processes of syphilitic origin.

One also encounters in syphilis, especially during therapy, fluctuating serologic reactions. A serum may be positive on a given day and but weakly positive or doubtful several days later or vice versa. Such results are naturally annoying to physicians. The fact, however, is that neither negative reacting sera nor strongly positive sera show a tendency toward marked fluctuations. Only sera giving borderline positive results may show this tendency, which might be due to the colloidal-chemical nature of the serologic tests employed. An outstanding feature of colloidal-chemical methods is that small variations in technique often lead to apparently marked changes in the results.

It is undoubtedly because serologic tests are based on colloidal surface reactions that we are faced with such large numbers of tests. The differences between the various precipitation tests are very much like the differences in the formula for baking a chocolate cake. The ingredients are very much the same, but the methods of mixing them are extremely important if one wants a really good cake. The same applies to the differences between the various complement fixation tests.

Since it is best that human ingenuity be stimulated rather than disturbed, it is just as well to be faced with the problem of increasing numbers of "new" serologic tests. Perhaps some day the perfect test will make its appearance. Even then, the problem of its performance by imperfect human hands will still remain.

In summarizing, we have seen that serology is intimately bound up with the immunology of syphilis; that serologic reactions in syphilis behave essentially like serologic reactions in other infectious diseases; that the same laws which govern serologic reactions in immunity apparently govern serologic reactions in syphilis; that all indications are that serologic reactions in syphilis are specific immune reactions.

III. SEROLOGY IN RELATION TO NONSYPHILITIC CONDITIONS

The serology of syphilis in relation to nonsyphilitic conditions presents a picture quite different from that just considered. One finds that serology is not merely a part of the immunology of a given infectious disease and serologic reactions are not necessarily associated with syphilis. Serology becomes a part of a biologic phenomenon not at all limited to infection and serologic reactions appear under multiple conditions in human beings and lower animals in the absence of syphilis. Let us consider these nonsyphilitic serologic reactions.

Ultramicroscopic Reaction Between Nonsyphilitic Sera and Tissue Extract Antigen.—Ultramicroscopic precipitation studies carried out in this laboratory⁴ showed that the type of antibody responsible for positive serologic reactions in

syphilis is widely distributed among human beings in the absence of syphilis. According to these studies, of a given number of sera giving negative serologic reactions, approximately one-third will show some precipitation with extract antigen when examined with the ultramicroscope. Table I gives the precipitation results obtained with 50 nonsyphilitic sera. It is evident that 17 of the sera showed a definite tendency toward precipitation with extract antigen. In this experiment the precipitation property of nonsyphilitic sera becomes evident only under conditions of high magnification. In the following experiment this precipitation property becomes evident without magnification.

TABLE I

SIZE OF AGGREGATES FORMED WHEN STANDARD ANTIGEN SUSPENSION (KAHN) IS MIXED WITH SERA FROM NONSYPHILITIC AND SYPHILITIC PERSONS AND EXAMINED ULTRAMICROSCOPICALLY

NUMBER OF SERA	CROSS-SECTIONAL AREA OF AGGREGATES IN SQUARE MICRONS	
	RESULTS READ	
	AFTER 1 HOUR	AFTER 6 HOURS
Nonsyphilitic		
11	0	0
13	0	10- 20
9	0- 10	20- 100
7	10- 50	100- 350
5	50- 250	350- 500
5	250- 500	500- 1,500
Syphilitic		
2	250- 500	500- 600
9	250- 500	600- 1,500
24	500- 3,000	1,500- 4,000
12	500- 3,000	4,000-10,000
3	3,000-10,000	10,000-25,000

Precipitation Property of Nonsyphilitic Sera With Highly Sensitive Antigens.—In the course of routine standardization of antigen in this laboratory during the past decade, antigens have been encountered many times more sensitive than standard Kahn antigen. Thus, in the University Hospital where serologic examinations are made routinely on all admissions, the number of positive reactions ranges between 3 and 4 per cent. With the especially sensitive antigens, however, the number of positive reactions in the same cases may exceed 30 per cent (Tables II and III).

TABLE II

SENSITIVITY OF STANDARD KAHN ANTIGEN COMPARED WITH THAT OF AN EXCESSIVELY SENSITIVE ANTIGEN*

Observed in routine standardization of antigen at the Serological Laboratory of the University of Michigan Hospital.

NUMBER OF SERA	STANDARD KAHN ANTIGEN	EXCESSIVELY SENSITIVE ANTIGEN
3	Positive	Positive
1	Doubtful	Positive
7	Negative	Positive
5	Negative	Doubtful
4	Negative	Negative

TABLE III

SEROLOGIC RESULTS GIVEN BY AN EXCESSIVELY SENSITIVE ANTIGEN COMPARED WITH THOSE GIVEN BY THE KAHN STANDARD AND PRESUMPTIVE ANTIGENS

Sera (504) taken from general run of hospital admissions.

ANTIGEN	POSITIVE	DOUBTFUL	NEGATIVE
Standard	15	3	486
Presumptive	20	2	482
Excessively sensitive	137	84	283

Serologic Reactions of Nonsyphilitic Sera From Patients With Leprosy and Malaria.—That serologic tests give positive reactions with the sera of patients with leprosy and malaria in the absence of syphilis is well known. Yet, it seemed worth while to summarize the serologic results obtained in these two diseases with thirteen different complement fixation and precipitation tests.⁷ It is evident from Table IV that leprosy patients give from 42 to 76 per cent positive serologic reactions and malaria patients, from 8 to 19 per cent positive reactions with different tests.

TABLE IV

FALSE POSITIVES REPORTED BY 13 DIFFERENT SEROLOGISTS ON BLOOD SPECIMENS FROM PRESUMABLY NONSYPHILITIC PATIENTS WITH LEPROSY AND MALARIA

(From Supp. No. 1, Ven. Dis. Infor. Washington, D. C., 1935.)

	LEPROSY—50 CASES	MALARIA—36 CASES
	PERCENTAGE OF FALSE POSITIVES	PERCENTAGE OF FALSE POSITIVES

*Performed modification of complement fixation tests. All others performed flocculation tests.

†Performed Kahn presumptive tests.

‡Performed Kline exclusion tests.

Nonsyphilitic Conditions in Which Positive Serologic Reactions May Be Obtained.—It is generally assumed, based on textbook reports, that false positive reactions may be obtained only in isolated pathologic conditions (in addition to leprosy and malaria), such as in infectious mononucleosis and malignancy. A study of the reports of the serologic evaluation studies since 1928 reveals, however, that false positives may be obtained in many pathologic conditions and also now and then under apparently normal conditions. The reports of the League of Nations Health Organization of the Copenhagen (1928)⁸ and Montevideo (1930)⁹ serologic conferences list among the conditions in which false positives have been obtained: acute bronchitis, psoriasis, acute cerebral hemorrhage, dementia praecox, epilepsy, senile cachexia, measles

headache, and many others. It might be added that the pathologic conditions in which false positives were obtained in the American Evaluation study of 1934-1935⁷ include, aside from leprosy and malaria, tuberculosis, malignant neoplastic disease, acute febrile diseases, and jaundice. False positives occurred also in pregnancy, during menstruation, and in other apparently normal conditions.

Positive Serologic Reactions in Lower Animals in the Absence of Syphilis.—It is well known that many of the lower animals give positive serologic reactions. It does not matter what particular method one employs, whether a complement fixation or a precipitation test, the reactions with the sera of horses, cows, pigs, chickens, and other animals are positive in most instances. Table V illustrates the relative frequency of positive serologic reactions given by lower animals. Table VI shows that lower animals may give positive reactions of relatively high quantitative titers.

TABLE V
POSITIVE KAHN REACTIONS IN NORMAL ANIMALS

ANIMAL	NUMBER OF BLOOD SERA TESTED	POSITIVE REACTIONS	NEGATIVE REACTIONS
Rabbit	29	21	8
Horse	21	19	2
Hog	42	42	0
Sheep	10	10	0
Cow	7	7	0
Calf	4	0	4
Dog	9	1	8
Chicken	54	32	22

	1	80
Hog	10	40-80
	10	120-200
Cow	6	40-80
	1	160

Are Serologic Reactions With Spirochetal Antigens More Specific Than With Tissue Extract Antigens?—Beck,¹⁰ in a recent comparative study of spirochetal and tissue extract antigens in complement fixation tests, found the two antigens of similar specificity. In 496 nonsyphilitic sera, he reported 1.6 per cent doubtful or positive reactions with a spirochetal antigen and 1.2 per cent with a tissue extract antigen. More recently, Eagle and Hogan¹¹ and Erickson and Eagle¹² have also made comparative studies of the two types of antigens and their results are definitely in favor of the spirochetal antigen (Reiter strain). Out of a group of 540 hospital cases which gave negative flocculation and complement fixation (Eagle) reactions, 17 gave reactions with

spirochetal antigen. Of these, 14 were accompanied by a history of syphilis, and only three were probably nonspecific.

These investigators also consider the nature of the antigen and antibody in the serologic tests with tissue extract and spirochetal antigens. According to Beck, the spirochetes contain a specific antigen and an "ubiquitous lipid substance," evidently common in mammalian tissue. Syphilitic serum contains two different antibodies: one reacting with the specific antigen in the spirochetes and the other with the lipid antigen. Beck demonstrated by means of absorption tests three corresponding antibodies for three serologically different types of spirochetes (Reiter, Kroo, and Noguchi). Eagle and his associates find that the absorption of syphilitic serum with spirochetal suspensions renders the serum serologically negative to both spirochetal and tissue extract antigens. On the other hand, the absorption of syphilitic serum with tissue extract renders the serum serologically negative to tissue extract antigen but not to spirochetal antigen. These authors conclude that spirochetal cultures (Reiter) contain antigenic material serologically related to a substance present in mammalian tissue, as well as other antigenic factors not present in such tissue. To quote Erickson and Eagle: "Since suspensions of cultured spirochetes contain antigenic factors which react specifically with syphilitic serum, some of which are not present in ordinary Wassermann and flocculation antigens, they may prove even more valuable than tissue extracts in the serodiagnosis of syphilis."

Returning to the question of specificity of spirochetal antigens, one might expect that the use of such antigens would lead to results very nearly completely specific for syphilis. For example, in the absence of syphilis in leprosy and in malaria, the results with such antigens should be negative. Yet, a serologic study of leprosy by means of the complement fixation test with spirochetal antigen by Cappelli,¹³ indicates that the use of this antigen does not assure absolute specificity. Of 23 nonsyphilitic leprosy patients studied, Cappelli reported 18 one-plus or two-plus reactions on the first reading, and 5 one-plus reactions on the second reading. It is thus evident that nonsyphilitic leprosy patients give at least weak or moderate complement fixation reactions with spirochetal antigen.

In the case of complement fixation tests with spirochetal antigen in malaria, in the absence of syphilis, Eagle¹⁴ has pointed out that the results, so far as specificity is concerned, are similar to those given by complement fixation and flocculation tests with tissue extract antigens. It is difficult to explain why serologic tests with spirochetal antigen should give false positive reactions in malaria. Perhaps it is the "ubiquitous lipid substance" of Beck present in the bodies of the spirochetes that is responsible for the positive reactions both in malaria and leprosy. Eagle also claims that spirochetal suspensions contain antigenic material "related to a substance present in mammalian tissue." Thus one must conclude that, based on present studies, spirochetal antigens, although apparently somewhat more sensitive than tissue extract antigens used in diagnostic tests, are no more specific than these antigens.

Why False Positives?—The positive serologic reactions in syphilis are not difficult to explain. We have already seen that in all probability they are intimately related with immunity in syphilis. If we accept the point of view that tissue extracts have something in common with the antigenic structure of the spirochetes, the immune nature of serologic reactions becomes further understandable. However, none of these views throws light on the basis of serologic reactions in the absence of syphilis. If we would meet with false positives only in malaria and leprosy, the problem would not seem so complex. But such reactions are met with in any type of pathologic condition and in the apparent absence of such condition. In addition, many of the lower animals give false reactions.

Elsewhere¹⁵ I have stated it is conceivable that the basis for these serologic reactions (in lower animals) is the likelihood that the animals are carriers of nonpathogenic spirochetes. Man, for example, is known to give low titer agglutinin reactions to typhoid bacilli without regard to typhoid infection or vaccine immunization. The explanation is that the colon and typhoid bacilli possess certain antigenic constituents in common, and man, being a carrier of colon bacilli, possesses some natural antibodies against typhoid bacilli. On the same basis it might be assumed that lower animals possess natural antibodies against spirochetes.

However, even if there is some basis of fact in this explanation of positive reactions in animals, it apparently is not applicable to false positives given by man. For these positives generally correspond to some pathologic disturbance. A patient with jaundice, for example, might give a positive reaction, but on recovery, this reaction generally becomes negative.

There is still another aspect with regard to false positives; namely, the type of test employed. Recognizing that traces of *reagin* commonly occur in sera of human beings, it is understandable why the sensitivity of a test is so interrelated with its specificity. Thus, when employing a dependable diagnostic test, sera containing minute amounts of antibody are likely to give reactions that are either negative or so close to the negative level as to be reported negative. If the sensitivity of a test is increased beyond proper limits, traces of antibody may be sufficient to give definitely positive reactions. Hence, highly sensitive methods are likely to give comparatively large numbers of false positives.

It should be stated that we have not been concerned here with technical errors in the performance of serologic tests leading to false positives. Our concern has been the so-called biologic false positives and, to our knowledge, there is no acceptable explanation for their existence.

To summarize, experimental evidence is presented that the type of reaction which occurs in the serology of syphilis is not limited by this disease. By means of ultramicroscopic studies and by the use of excessively sensitive antigens, it can be shown that relatively large numbers of nonsyphilitic individuals may give positive reactions. It is also well known that nonsyphilitic individuals with various pathologic conditions may give positive reactions with routine diagnostic tests. The same tests also give positive reactions

with the sera of different animals in the absence of syphilis. It is thus evident that serologic reactions in the absence of syphilis are not isolated and unique, but they represent a distinct and widespread biologic phenomenon.

IV. DIFFERENTIATION BETWEEN SEROLOGIC REACTIONS IN SYPHILIS AND IN THE ABSENCE OF SYPHILIS

Assuming that it were possible to distinguish serologic reactions occurring in syphilis from those occurring in the absence of this disease, serology would be placed on a new scientific foundation. The serology in syphilis and in the absence of syphilis would then become distinct from one another. The serology in syphilis would assume new specificity, hence, new dependability; and the serology in the absence of syphilis would lend itself to special studies as to its *raison d'être*. These were the thoughts that for many years kept studies on the detection of false positives alive in this laboratory, but only recently did these studies begin to show promise.

Strange as it may seem, the basis for the detection of false positives lies within the very serologic procedures in common use. The factor which differentiates true from false positives is the temperature at which these serologic procedures are carried out.

It is well known that the temperature at which serologic tests are performed markedly affects the final results. In the case of the standard Kahn test which is performed at room temperature, it has been observed again and again that high room temperature and low room temperature do not lead to the same results. Generally, temperatures considerably above 21° C. lead to increased sensitivity, and temperatures considerably below 21° C. lead to decreased sensitivity. But these observations apparently apply only to syphilitic sera.

Studies of the effect of temperature on the Kahn reaction with animal sera were found to present a different picture. These sera tend to give more marked precipitation at temperatures below 21° C. than at temperatures above 21° C.

This difference in the response to temperature by seropositive syphilitic and animal sera formed the basis of studies which led to the development of a procedure for the detection of false positive reactions in man. This procedure consists in performing the standard Kahn test at 37° and 1° C., respectively. The technique is described elsewhere.¹⁶ Herewith, we shall limit ourselves to brief considerations of several observations brought to light by this differential temperature procedure.

Observation 1. Serologically positive sera of lower animals react more strongly at 1° than at 37° C. Serologically positive sera from horses, cows, pigs, rabbits, and other animals, when examined with the standard Kahn test, carried out at 37° and 1° C., respectively, give stronger precipitation reactions at 1° than at 37° C. The types of reactions obtained at these two temperatures depend on the serologic potency of the sera. Some sera are moderately positive in the cold and negative at 37° C.; some are strongly positive in the cold and negative or moderately positive at 37° C.; those which are so potent as to be strongly positive at both temperatures can be rendered positive in the cold and negative at 37° C. at given dilutions of the serum with salt solution.

Observation 2. Serologically negative sera of lower animals are either negative at 37° and at 1° C., or are negative at 37° and positive at 1° C. The tendency of animal sera to give precipitation reactions in the cold is not limited to those sera which are positive with a serodiagnostic test. The same tendency is noted also with sera which are negative with a serodiagnostic test. When such sera are serologically examined at 37° and 1° C., approximately one-half will be found to give positive precipitation reactions at 1° and negative reactions at 37° C.; the remainder are negative at both temperatures.

Observation 3. Serologically positive syphilitic sera react more strongly at 37° than at 1° C. When syphilitic sera giving positive reactions with a serodiagnostic test are examined serologically at 37° and 1° C., precipitation will be found to be marked at 37° and weak or negative at 1° C. In the case of syphilitic sera having a high serologic titer, the reactions at 37° and 1° C. may be similarly positive. If such sera are first diluted with salt solution to a degree that they give weakly positive reactions with a diagnostic test, and are then examined at the differential temperatures, precipitation will be marked at 37° and weak or negative at 1° C. As will be seen below, the behavior of syphilitic sera at the differential temperatures is not as consistent as the behavior of animal sera at these temperatures.

Observation 4. Some serologically negative syphilitic sera are positive at 37° and negative at 1° C. When serologically negative sera from treated cases of syphilis are examined at 37° and 1° C., some will be found to give a positive precipitation reaction at 37° and no reaction at 1° C. Now and then a serologically negative serum will show similarly weak precipitation at both of the differential temperatures.

Observation 5. Serologically positive nonsyphilitic sera react more strongly at 1° than at 37° C. (a) *Malarial Sera.* An opportunity was afforded us to study the serologic behavior of malarial sera at the differential temperatures. The study was undertaken by Dr. L. E. Burney of the United States Public Health Service and Dr. J. R. S. Mays, Assistant Physician of the Milledgeville State Hospital, Milledgeville, Ga. Various syphilis-free patients in this hospital were treated by inoculation with malaria, and the serologic reactions were studied before, during, and after the malarial paroxysms. A number of these patients gave positive serologic reactions with diagnostic tests. When testing the serologically positive sera of these patients at the differential temperatures, they showed stronger precipitation reactions at 1° than at 37° C.

(b) *Leprosy Sera.* Some serologically positive leprosy sera show stronger reactions at 37° than at 1° C., and others show stronger reactions at 1° than at 37° C. It is likely that the former sera are from patients who have syphilis in addition to leprosy, and the latter are from patients who have only leprosy. In view of the fact, however, that it is extremely difficult to differentiate clinically syphilis from leprosy in many instances, the interpretation of these serologic findings at the differential temperatures must be held in abeyance.

(c) *Miscellaneous Sera.* Serologically positive sera in which the reactions are believed to be false are frequently being received in this laboratory for examination from all over the United States. Many of these sera show strong

precipitation at 1° and negative precipitation at 37° C., and when the clinical histories of these cases are sent to this laboratory, all indications point to the absence of syphilis. Occasionally, this type of precipitation is obtained with a serum from a febrile patient giving a positive reaction with a serodiagnostic test during the febrile period, but a negative reaction when the fever subsides. Recently a specimen of blood from a 17-year-old boy was examined at the differential temperatures. The boy won a scholarship in one of our leading institutions of learning and was clinically free from any suggestion of syphilis. The finding of a stronger precipitation at 1° than at 37° C. with this boy's serum led us to report a nonsyphilitic type of reaction.

Observation 6. Serologically negative nonsyphilitic sera are either negative at 37° and at 1° C., or are negative at 37° and positive at 1° C. Serologically negative nonsyphilitic sera might be expected to be negative also at 37° and 1° C. Actually, many of these sera give precipitation reactions at 1° C. The number of these reactions in the cold depends on the source of the sera. In the case of normal persons these reactions may not exceed 2 per cent. In hospital cases they may reach 4 per cent or higher. In leprosy and malaria these reactions in the cold have been found to reach as high as 50 per cent. Table VII summarizes Observations 1 to 6 in outline form.

TABLE VII

RESULTS GIVEN BY THE DIFFERENTIAL TEMPERATURE TECHNIQUE (VERIFICATION TEST)
WITH VARIOUS SERA

SERUM NUMBER	REACTION OF SERODIAGNOSTIC TEST	PRECIPITATION RESULTS:					
		37° C.			1° C.		
		Tube 1	Tube 2	Tube 3	Tube 1	Tube 2	Tube 3

1	Negative	-	-	-	-	-	-
2	Negative	-	-	-	++++	++++	++++
3	Negative	-	-	-	-	+	+++

Observation 7. Exceptions. The foregoing observations indicate that positive serologic reactions given by serodiagnostic tests are divisible into two broad types: a syphilitic type and a nonsyphilitic type. Sera giving the former

type of reaction tend to give stronger serologic results at 37° than at 1° C., while sera giving the latter type of reaction, tend to give stronger serologic results at 1° than at 37° C. In view of the fact that the nonsyphilitic type of reaction is encountered under various conditions in man and is relatively widespread among lower animals, it is referred to as the general biologic type of reaction.

But clear-cut syphilitic and general biologic types of serologic reactions are not the only types encountered in practice. Serologically positive human sera may show both types of reactions. Considering the widespread distribution of the general biologic type of reaction in the absence of syphilis, there is no reason why it should not also be found in the presence of syphilis. Hence, it might be expected that certain cases of syphilis might give at the same time both the syphilitic and the general biologic types of reactions.

Then again, the general biologic type of reaction may occur in syphilis; as has been observed in this laboratory in cases of neurosyphilis treated with malaria. A patient may show a positive spinal fluid reaction and a weakly positive or negative serum reaction. During malarial therapy he may begin to give strongly positive serum reactions with a diagnostic test. On examination of the serum at 37° and 1° C., it is found that the reactions are strongly positive at 1° and weakly positive or negative at 37° C., indicating that these reactions are not related to syphilis, but to the malaria therapy.

In those instances in which the results of the differential temperature technique are inconclusive, certain supplementary procedures may prove of assistance. A procedure most frequently employed is based on the observation that sera giving borderline positive serologic reactions of a nonsyphilitic nature tend to show precipitation not only at 1° C. after they have been heated for thirty minutes at 56° C., but also in an unheated state. Syphilitic sera giving borderline positive serologic reactions differ in this respect. These weakly positive sera give little or no precipitation in the cold after they have been heated at 56° C., and they are especially likely to give no precipitation in the cold when tested in an unheated state. Hence, when the results of the differential technique are inconclusive, a supplementary test is carried out with serum in an unheated state. If precipitation is obtained at 1° and no precipitation at 37° C., the probability is that the serologic reaction is of a nonsyphilitic type. The use of sensitized antigen (employed in the Kahn presumptive test) has also thrown light on a number of inconclusive types of reactions obtained with standard antigen. Studies of supplementary procedures are in progress with the aim of reducing to a minimum the number of inconclusive types of reactions with the differential temperature technique.

The Verification Test.—The differential temperature technique is referred to as the verification test. The value of this test is briefly twofold: 1. As a supplementary procedure for serodiagnostic tests whenever there is a question of false positives. 2. As a procedure for the study of the nature and significance of positive serologic reactions in the absence of syphilis.

The verification test as a supplementary serodiagnostic procedure. Whenever there is a question of the specificity of a positive reaction given by a

diagnostic test, the serum is examined with the verification test. Three types of reactions are likely with this serum:

1. Syphilitic type.
2. General biologic type.
3. Inconclusive type.

When sera giving negative reactions with a diagnostic test are examined with the verification test, four types of reactions may be noted.

1. Negative type (when no precipitation occurs at either 37° or at 1° C.).
2. General biologic type.
3. Syphilitic type (generally in treated cases of syphilis).
4. Inconclusive type.

The verification test in the study of the nature and significance of non-syphilitic serologic reactions. False positive serologic reactions are generally considered in relation to syphilis only. Once it is established that a given reaction is a false positive, the matter is generally dismissed. The question may arise, why it is that false positives in man are almost invariably associated with pathologic disturbances. In leprosy, malaria, and infectious mononucleosis these general biologic types of serologic reactions are encountered more frequently than in other pathologic conditions. Also, why it is quite rare to encounter these types of reactions in the absence of pathologic conditions. The fact that the general biologic types of reactions are encountered among serologically negative persons is also of great interest. Can it be said that the general biologic type of reaction in man is a manifestation of some disturbance, or do certain persons have the tendency to give this type of serologic reaction without regard to any disturbance?

V. SUMMARY—THE NEW SEROLOGY OF SYPHILIS

Indications are that the serology of syphilis, as it has developed during the past three decades, embraces two distinct types of positive reactions. One is essentially an immune serum reaction, similar to agglutination, precipitation, and other antigen-antibody reactions in immunity, which apparently is specifically associated with syphilis. The other type of reaction may or may not be associated with immunity; in lower animals it occurs under apparently normal conditions; in human beings it most frequently occurs under pathologic conditions, but it is definitely not associated with syphilis.

In the new serology of syphilis, every positive reaction in which there is a question as to its relationship to syphilis will be subjected to special studies, not alone with the verification test but also, should it prove necessary, with all possible supplementary procedures. The serologist then will assume full responsibility for his report just as the roentgenologist, for example, is responsible for his.

Should the serologic reaction be found to be of the general biologic type and unrelated to syphilis, clinicians will not disregard it, but will investigate the reason for this reaction, especially as to whether some pathologic condition is responsible for it. Repeated serologic studies might reveal an increase or a decrease in the potency of the reaction, and these changes might correspond to

changes in the pathologic condition. Then again, the studies might reveal, in some cases, a tendency toward positive serologic reactions in the apparent absence of pathologic conditions.

The new serology of syphilis will thus lead not only to more dependable laboratory diagnosis in syphilis, but also to the study of the significance of those reactions not associated with this disease. A positive serologic reaction in the diagnosis of an asymptomatic case will first of all require the "typing" of the reaction to determine whether it is syphilitic or general biologic. This determination may necessitate repeated serologic studies, considering that a person who shows no signs or symptoms of syphilis is to be diagnosed as syphilitic or as free from syphilis. The increased dependability of the serologic diagnosis of syphilis should remove objections against routine blood testing. This step, in turn, should greatly aid the control of syphilis.

THE TAKATA-ARA TEST IN LIVER DISEASE*

THOMAS BYRD MAGATH, PH.D., M.D., ROCHESTER, MINN.

HISTORICAL DATA

WERE a student to seek an example in medical literature of generosity and patience on the part of investigators, he would do well to examine the case of the Takata-Ara test. He would discover in the vast number of papers on the subject, of which with comparative ease might be found more than a hundred, what has come to be the typical life history of a laboratory test in modern medicine. This includes, among other things, the obsession of devising and using a simple, and if possible, bedside test to make an absolute and never failing diagnosis in an extremely complicated and involved disease of diverse manifestations. Perhaps it is the medical equivalent of the desire to get something for nothing.

The history of the test might at once arouse suspicions. It was reported^{75, 76} at a meeting of the Far Eastern Association of Tropical Medicine for study of four widely separate diseases, no one of which may be considered as being tropical. The relative rarity of the parent publications suggests that few authors have ever consulted it. It is fair to conclude that so far as American authors are concerned, they have been content to quote from Crane that it was originally proposed by Takata "and later by Takata and Ara in 1925 as a colloid reaction in chest fluid." So far as the printed records are concerned, Takata and Ara,⁷⁵ not Takata,⁷⁶ first recorded the reaction in what may be called a prior publication, for the page is 667. Here the test was described for spinal fluid as diagnostic for syphilis and meningitis. On a later page, namely 693, and at the same meeting, Takata⁷⁶ reported on the use of the same reaction in chest fluid but in a different technical setting, to distinguish between lobar and lobular pneumonia.† So far as can be determined, study of the test has not been extended seriously in these connections. It is important to note that Takata thought the flocculation or precipitation of the mercuric salt was due to an increase in globulin, long considered the agent which causes the precipitation of various colloidal suspensions, as for example, gold sol and benzoïn.

*From the Division of Clinical Pathology, Section on Parasitology, the Mayo Clinic, Rochester.

†It would probably be useless to attempt to obtain general agreement as to the proper name for the test if an eponym is to be used. The particular reaction resulting in a positive test may, with considerable justification, be first ascribed to Takata and Ara, since their paper preceded the paper by Takata in the volume. The serial dilution idea was also considered in the paper by Takata and Ara. However, in a limited circulated volume of abstracts of the scientific papers presented at the Sixth Congress of the Far Eastern Association of Tropical Medicine and published in Tokyo in 1925, there appeared extensive abstracts of the two papers in question. The one by Takata appeared on pages 585 to 590, while the one by Takata and Ara appeared on pages 609 and 611. The papers were evidently read at the same session and both were read by Takata, who stated that he had first used the test in the study of pneumonia. On the other hand, in neither paper was it suggested that the reaction be used as a liver function test. This was suggested by Staub,⁷² but the method of performing the test was published by Jezler.^{40, 41} It seems wise to refer to the test as the Takata-Ara test since the literature generally contains the two names linked together.

Staub⁷² knew that Adler and Strauss had shown the presence of a disturbance in the albumin-globulin ratio in the serum of persons suffering from certain liver diseases, and that Abrami and Robert-Wallich had shown it in cirrhosis in particular. He suggested to Nicole that he investigate the cause of the Takata-Ara reaction in spinal fluid, and Nicole concluded it was due to a shift in the albumin-globulin ratio. Staub then suggested to Jezler that the Takata-Ara test could be used as a liver function test on blood serum. Indeed, Staub reported that the results of the test were positive in cirrhosis, but the protocols and details were supplied by Jezler^{40, 41} the next year in his report which included a modification of the technique and a demonstration that the test could be performed on ascitic fluid. In 42 cases of cirrhosis he obtained 38 positive reactions, but he also obtained some positive reactions in pseudocirrhosis, yellow atrophy, chronic alcoholism, and passive congestion of the liver.

TABLE I

TAKATA-ARA REACTION IN CASES OF CIRRHOSIS OF THE LIVER

AUTHOR	CASES	POSITIVE REACTIONS	
		NO.	PER CENT
Jezler	176	124	70
Storz and Sehlunbaum	4	3	75
Oliva and Pescarmona	17	17	100
Skouge	40	38	95
Zadek and co-workers	6	6	100
Rohrer	15	14	93
van Ginkel	21	16	76
Crane	25	20	80
Schindel	13	12	91
Lazzaro	29	27	93
Schindel and Barth	13	12	92
Heath	77	46	60
Hafström	18	17	94
Ragins	59	57	97
Ling and Gsellmann	12	12	100
Rappolt	73	61	84
Maneke and Margaronis	66	64	97
Kirk	21	15	71
Bowman and Bray	21	18	86
Tumen and Bockus	19	15	79
Cuttle, Kerr, Wolff	18	17	94
Girard and Vincent	20	20	100
Payne	71	61	86
Heinrici	52	47	90
Horejsi	18	13	72
Israel and Reinhold	72	61	85
Wayburn and Cherry	94	87	93
Gertler and Lachenicht	21	14	67
Golob and Nussbaum	72	53	74
Gray	35	28	80
Magath	72	43	60
Total	1270	1038	82

Bauer⁵ found the test fairly satisfactory with some positive reactions in the presence of catarrhal jaundice and some negative results in cirrhosis. Storz and Sehlunbaum studied a number of cases and obtained positive reactions in 3 out of 4 cases of hepatic abscess, 3 out of 4 of cirrhosis, in 1 out of 23 of cholecystitis, and 1 out of 13 of heart failure and jaundice. Oliva and Pescarmona expressed the belief that the test is specific for cirrhosis, and this opinion has been shared by many.

For several years after this the main development of the test was along the line of demonstrating its specificity for the diagnosis of cirrhosis. In evaluating the material as a whole the fact appears that many different criteria have been used for reading a positive reaction, and that what was called a significantly positive reaction by one author is called a negative result by another. Hence the comparison of percentages in Table I must be accepted with some reservations. Furthermore, the diagnoses may be disputed in some instances, since evidence frequently was not recorded.

A careful examination of the reports, however, discloses a significant fact. In early cases of cirrhosis the Takata-Ara test frequently gives a negative result, and only in the advanced cases, usually with ascites, can it be relied on to give a positive reaction. Hence the percentage of positive reactions in a series of cases of cirrhosis may be varied by the inclusion of an excess of early or late cases. Naturally in the cases in which necropsy confirmed the presence of cirrhosis, the results of the test were almost invariably positive. In summary, the impression gained from an extensive examination of literature leads to the conclusion that in less than half of the cases of early cirrhosis a strong positive reaction will be obtained, and in a high percentage, probably 90 or 95 per cent, of the cases of late cirrhosis the results of the test will be positive.

The enthusiasm for the test, even as a diagnostic one for cirrhosis, would not have been so great if critical examination of the protocols and even the conclusions of the majority of authors had been made. It has now become apparent that parenchymatous damage of liver cells, if severe or even moderately severe, will cause a positive Takata-Ara reaction in a large percentage of cases. This damage may be caused by a wide variety of agents. It is important to know that many authors, in fact almost all who have investigated the matter, have shown that changes in the liver attributable to obstructive jaundice, even though the jaundice be severe, do not, as a rule, produce a positive Takata-Ara reaction. Crane has shown this in 18 cases; Jezler,^{40, 41} in many cases; and the same observation has been made by Storz and Schlunbaum, Wayburn and Cherry, Heath, Sommer, von Brandis, Magath, and others. Yet Gertler and Lachenicht found the test positive in all nine of their patients with "icterus simplex."

Many authors have recorded many positive reactions in the presence of parenchymatous damage of the liver which was not due to obstructive lesions. Some authors, such as Sommer, Gohr and Bolt, and Backert and Naville, have been so impressed with this that they have implied that the test may be used as an indication of such damage. Mancke and Sommer, Rathery and Ferroir, Godtfredsen, Sparchez and Viciu, Magath, Gertler and Lachenicht, Cañizo, Cornejo, and Irigoyen, and others have emphasized the frequency with which the test gives positive results in this type of hepatic injury. Such conditions so far recorded are hepatitis due to a variety of causes, abscesses, passive congestion, malignancy, hepatic syphilis, acute yellow atrophy, and possibly other conditions. Hugonot and Sohler³⁷ reported the test positive in two cases of leishmaniasis and thought the test would be positive in grave hepatic disease. Unanimity of opinion is not found among all authors, however, in regard to

this matter. For example, Crane did not find any positive reactions in 6 cases of malignancy of the liver and even thought the test could be used to advantage in identifying these cases. Von Brandis tested 30 patients with malignant disease of the liver and obtained negative results for all, yet Heinrici obtained 10 positive reactions in 12 cases. Jezler¹¹ in one series obtained positive reactions in 1 out of 6 cases studied; I found positive reactions in 7 out of 9 cases; Gertler and Lachenicht reported positive tests in 9 out of 11 cases; and Payne found 9 positive tests out of 14 cases of malignancy. Chasnoff and Solomon¹² concluded the Takata-Ara test was positive in most cases of malignancy involving the liver. Disagreement in regard to the test in passive congestion owing to cardiac failure and other conditions has also been recorded. Heinrici recorded positive reactions in half of his cases, and Horejsi, in a smaller percentage. Girard and Vincent obtained routinely negative reactions, and Storz and Schlungbaum rarely found a positive reaction. Crane recorded a few positive reactions, and Wayburn and Cherry obtained positive reactions in 7.4 per cent of their 122 cases.

In spite of many discrepancies in results, the general opinion has been that the test is useful in the diagnosis of cirrhosis. Some authors, however, have not agreed with even this general statement. Bowman and Bray stated the test was "not significant enough to be of value in the clinic as an additional laboratory procedure," and they obtained a large number of positive reactions on patients without cirrhosis whose total proteins were low or whose albumin-globulin ratios had shifted.

Many authors have recorded positive reactions in diseases not essentially hepatic in nature and even in diseases in which the liver can hardly be regarded as being essentially involved. Examples of these which may be mentioned are the positive reactions obtained in 13.4 per cent of cases of stomach ulcers, colitis, and pulmonary tuberculosis recorded by von Brandis, and in 11 out of 12 cases of pulmonary tuberculosis listed by Ornstein. Ornstein also found a high percentage of positive reactions in cases of nephritis, pellagra, secondary syphilis, chronic alcoholism, and diabetes, and even 27 per cent of positive reactions in mental maladies. Positive reactions in nephritis, pulmonary tuberculosis, arteriosclerosis and lobar pneumonia were found by Crane. Schmengler also found positive reactions in a high percentage of cases of pulmonary tuberculosis. In all cases of nephritis studied by Wayburn and Cherry positive reactions were obtained, and positive reactions also were recorded in cases of lobar pneumonia and pulmonary tuberculosis. Biondo found positive reactions in two cases of pulmonary tuberculosis and atrophic changes in the liver. Girard and Vincent emphasized the likelihood of positive reactions in the presence of nephritis with low serum proteins, and others have recorded occasionally positive reactions in a variety of diseases. Weiner also obtained positive reactions in nephritis. Banti's disease has not given consistent reactions in the hands of various authors; some recorded positive reactions and others negative ones.

Hirsch, after observing the test in a long series of children, concluded that the test was more than a liver function test; that its results were positive in all serious diseases in which the detoxicating function of the liver was disturbed or

the colloidal state of the serum was changed. This among children occurs frequently in such diseases as typhoid fever, pneumonia, nephritis, and in septic conditions.

It is interesting to note that Bauer,⁶ and more recently Gray, have reported on colloidal gold tests on serum of patients with hepatic disease. They have found in general that positive reactions are the rule in cases of cirrhosis and acute parenchymatous hepatic disease, and occur in many cases of malignancy of the liver and various hepatic diseases. This colloidal gold test was found to give a positive reaction in certain extrahepatic diseases and in particular in syphilis. The test appears to be more sensitive than the Takata-Ara test as a general liver function test and hence less specific for cirrhosis. Gray thought the test did not depend primarily upon a quantitative increase in globulin, a decrease in albumin, or an inversion of the albumin-globulin ratio. He was of the opinion that euglobulin was the key to the reaction.

METHOD

The technique described by Takata⁷⁵ required eleven tubes. One cubic centimeter of patient's serum was so diluted with physiologic salt solution that a serial dilution resulted as follows: 1:5, 1:10, 1:20, to 1:500. To each tube were added 0.25 c.c. of 10 per cent solution of sodium carbonate and 0.25 c.c. of a fresh mixture of mercuric chloride solution, consisting of equal parts of 0.5 per cent sublimate solution and 0.02 per cent fuchsin. The tubes were allowed to stand for several hours, and positive results were indicated by flocculation in the tubes. Jezler⁴¹ modified the test by using nine tubes and making a serial dilution beginning with 1 c.c. of serum and 1 c.c. of salt, in the proportion of 1:2, then 1:4, 1:8, to 1:512. To these dilutions were added 0.25 c.c. of 10 per cent solution of sodium carbonate and 0.3 c.c. of sublimate fuchsin mixture. The reading was made after a half hour and again after five hours, and positive reactions were indicated when at least three tubes of 1:32 dilution or higher showed flocculation. Takata and Ara used a single tube into which were placed 1 c.c. of spinal fluid, 1 drop of 10 per cent solution of sodium carbonate, and 0.3 c.c. of a mixture of 0.5 per cent solution of mercuric chloride and 0.02 per cent solution of fuchsin. The tube was shaken and allowed to stand for twenty-four hours. They also proposed the serial dilution scheme.

Since Takata and Ara announced their test a large number of modifications have been introduced. One which has been used extensively and which was used in my previously reported series was a modification proposed by Heath. For this test six tubes are used, and into each is placed 1 c.c. of 0.9 per cent solution of sodium carbonate. To the first tube 1.0 c.c. of serum is added, and the contents are thoroughly mixed. One cubic centimeter then is removed and added to the second tube. After mixing, 1.0 c.c. is transferred from the second to the third tube, and so on until the sixth tube, from which 1.0 c.c. is discarded. The dilutions of serum thus range from 1:2 to 1:64. To each of the tubes 0.25 c.c. of 10 per cent solution of sodium carbonate is added, and the contents are well shaken. Then 0.15 c.c. of solution of mercuric chloride is added to each tube, and the tubes are again shaken. The mixtures are allowed to stand at room temperature overnight, and the readings are made at sixteen to twenty-four hours. Heath

divided the reactions into five groups: strongly positive, positive, weakly positive, suspicious, and negative. A strongly positive reaction is characterized by a maximal precipitate on settling, filling at least the lower third of the fluid column. A positive reaction occurs when there is a definite but not a maximal precipitate in any one tube, or some precipitate in at least three tubes. A weakly positive reaction is present when there is a definite but minimal precipitate in any one or two tubes, and a suspicious reaction is present when there is a doubtful precipitate in any two tubes. The reaction is considered negative when there is no flocculent precipitate. A definite, pearly flocculent precipitate must be present to interpret a reaction as positive. Granular or flaky precipitates are disregarded.

Ueko's^{80, 81} modification consisted of using four tubes, into each of which is placed 0.2 c.c. of serum; and into the first tube, 0.25 c.c. of 0.36 per cent solution of sodium carbonate; into the second tube, 0.2 c.c.; into the third, 1.5 c.c., and into the fourth, 1 c.c. Solution of mercuric chloride, 0.5 per cent, is added to each tube in amounts equal to the carbonate solution. If three or more tubes are translucent after they have stood for several hours, the reaction is said to be negative. If there is an opaqueness with some precipitate in the first three tubes, it is graded 1+. If there is a precipitate or flocculation of uniform turbidity in the four tubes, it is graded 2+; and if a thick precipitate forms immediately in all four tubes, the reaction is graded 3+. Ueko⁸¹ thought his modification gave a more certain indication of disturbance of the liver than did the Takata test, and on comparison obtained about 20 per cent disagreement between the two tests. Bauer⁵ used magnesium chloride instead of mercuric chloride.

Many suggestions for reading the results of the test have been proposed, as for example, the one by Hafström, who graded the results on a scale of 1 to 4: grade 1 being slight turbidity; grade 2, incipient flocculation; grade 3, clear flocculation; and grade 4, maximal flocculation. Hafström also used fuchsin in his tests.

Mancke and Sommer devised a modification which they advocated: Into each of eight tubes is placed 0.1 c.c. of the serum; then 1.0 c.c. of the salt solution (0.9 per cent) is put into the first tube, 1.1 c.c. in the next, and so on, until the last tube receives 1.7 c.c. Into each tube is placed 0.4 c.c. of a 10 per cent solution of sodium carbonate, and then 1.0 c.c. of 0.25 per cent solution of mercuric chloride is pipetted into the first tube and 0.9 c.c. in the second; the quantity is decreased by 0.1 c.c. until the last tube receives 0.3 c.c. The flocculation test is read after twenty-four hours.

Since Wayburn and Cherry indicated that their method of performing the test increased its accuracy, and since they did not altogether agree with my previous report, I decided in this new series to use their technique.* The method of Wayburn and Cherry is a modification of that proposed by Crane and is not unlike the method suggested by Heath: eight Wassermann tubes are used

*Both in the tables and text of Wayburn and Cherry's paper they indicated that I found 9 positive Takata-Ara reactions in 25 cases of cirrhosis of the liver, and in the table they indicated that the percentage of positive reactions was 36 per cent, which would have brought my results entirely out of line with all previous results. Evidently this is a misreading on the part of Wayburn and Cherry. In 16 or 64 per cent of my series of 25 cases of cirrhosis of the liver, the Takata-Ara reaction was positive. This may be compared favorably with Heath's 60 per cent and Kirk's 71 per cent, as reported in the table by Wayburn and Cherry.

instead of six, and the serum is serially pipetted in geometric dilutions. The tubes are agitated thoroughly for thirty to forty seconds after receiving 0.25 c.c. of 10 per cent solution of sodium carbonate, and the individual tubes are shaken as soon as 0.15 c.c. of a 0.5 per cent solution of mercuric chloride is added. The tubes are left at room temperature for twenty-four hours before reading. The presence of a characteristic precipitate is considered a positive reaction. This is a white to pearl gray, soft, large-flaked flocculent. The serum was not considered positive unless a precipitate appeared in at least three consecutive tubes. This usually begins in the 1:8 dilution. The appearance of a fine, brick-red precipitation is of no significance. Wayburn and Cherry admitted that the six tubes proposed by Crane were rational, although they thought the results are demonstrated more clearly with eight tubes. I did not notice the advantage of the two additional tubes.

Although the technique of performing the Takata-Ara test is superficially simple, careful study and experience in reading precipitation tests are necessary in order to secure satisfactory results. Frequently precipitation occurs that evidently is not colloidal flocculation and gives the inexperienced worker difficulty in interpreting the test.

MECHANISM OF THE TAKATA-ARA TEST

In spite of the vast literature which has accumulated concerning the mechanism of the Takata-Ara test, there is as yet no general agreement or adequate explanation for the flocculation that occurs in the serum of certain patients. In general, it is believed that mercuric chloride and sodium carbonate form mercuric oxide in the presence of proteins which are considered to act as protective colloids. In certain pathologic states precipitation of the colloid occurs because as is generally believed, the albumin-globulin ratio in the serum has been altered. Takata⁷⁰ thought that the ratio was altered by an increase in the globulin fraction. Jezler^{40, 41} found the globulin fraction regularly more than 55 per cent of the total protein in cases in which Takata-Ara reactions were positive; whereas in cases in which the results were negative the average was about 37 per cent.

Gros,²⁹ from a comprehensive study of the mechanism of the Takata-Ara reaction, concluded that mercuric chloride was adsorbed in organic substances onto the protein, but he did not think that this was specific for persons with diseases of the liver.

Many investigators have concluded that the precipitation by the alkaline sublimate solution was due to a disturbance in the albumin-globulin ratio, although many have noted that in a fairly large number of cases a positive Takata-Ara reaction has been obtained when the ratio was normal, and conversely, negative reactions have been seen when the ratio was disturbed. Some authors have stated that a mere lowering of the protein level did not result in flocculation, although Abrami and Robert-Wallich thought it did. Among those who have held that a change in the ratio between albumin and globulin resulting in a relative increase in globulin was the cause of the precipitation may be mentioned Lazzaro, Vigada and Montanari, Hugonot and Sohler,³⁶ Schreuder, Carrière, Martin, and Dufossé, Ragins, and Gohr and Niedeggen. Others, such as van

Ginkel, Gros,²⁸ Hahn, Rappolt, Kirk, and Ueko,³² indicated that an actual increase in the serum globulin must be considered important in causing the positive reaction.

In opposition to these opinions, Skouge, and Schindel and Barth were unable to correlate accurately the Takata-Ara reaction with either an increase in globulin or a lowering of the albumin-globulin ratio. Fulde thought there was no correlation between the albumin-globulin shift and the reaction. Schreuder took the half way position, that either an increase in globulin or a decrease in albumin would cause a positive reaction. When Kallos-Deffner starved rabbits in a rarefied atmosphere and produced a ketonuria in them, the Takata-Ara test then gave a positive result which became negative when the animals returned to normal; d'Alessandro corroborated these observations. Recht lent some support to this line of thought when he demonstrated the positive reaction of children with acidosis and dehydration.

Medvei and Paschkis, Zirm, and Ragins have noted that after the addition of heparin to blood, the serum which previously had given a positive Takata-Ara reaction gave a negative reaction; this occurred in spite of the fact that Fischer demonstrated heparin converts albumin in serum into globulin.

Bowman and Bray obtained many positive Takata-Ara reactions with serum in which the level of protein was low and in which the albumin-globulin ratio was not reversed.

Tumen and Bockus did not think that the reaction was wholly dependent on the albumin-globulin ratio, although they stated that a low albumin content and the reversal of the albumin-globulin ratio were the rule. The same conclusion was reached by Cuttle, Kerr, and Wolff. Chasnoff and Solomon,¹⁵ after studying 28 cases, concluded that in most cases there was an alteration in the albumin-globulin ratio when the Takata-Ara reaction was positive; although this was the most important cause of the reaction, it was not the sole cause.

Taran and Lipstein pointed out that the albumin levels are lower and the globulin levels are higher in serum with a positive reaction. In their series of 40 cases of amyloidosis and tuberculosis, Takata-Ara reactions were positive in 31. These authors, however, expressed the belief that this was not due to the presence of amyloid but to the changes in the relation of the serum proteins.

Schindel produced positive reactions by the addition of lower fatty acids to serum and reversed the reaction when he then added alkalis, yet Gros²⁸ could produce no changes in the test after extraction of fatty acids from the serum. Ueko³⁰ rightly criticized these experiments as being invalid, since the addition of fatty acids changes the reaction in the tubes to such an extent that the test is no longer comparable to the original test.

Oselein found the ammonia content of the blood high in cases in which the Takata-Ara reactions were positive. When the amount of ammonia was low, that is, from 0.2 to 0.58 mg. per 100 c.c., he found the reaction was negative. It was positive when the quantity of ammonia was above the level of 0.85 mg. per 100 c.c. Chasnoff and Solomon,¹⁵ after an exhaustive study of this factor, concluded the ammonia content of the blood bore no relation to the Takata-Ara test.

Horejsi contended that the globulin in the serum caused the precipitation in the Takata-Ara reaction when the globulin was not protected. He suggested

this protection was due to "some sulphuric compound in the blood serum," perhaps a free SH-group. He explained the reaction in hepatic disease on the theory that the sulfur metabolism was faulty in such diseases.

Seiler and Rehm maintained that this reaction was not a colloid-colloid reaction, but that the mercuric chloride in the Takata-Ara test was in a true solution, entering into the protein complex and remaining as a sublimate or oxychloride. They were of the opinion that the flocculation was primarily a pH reaction present in pathologic sera.

Staub and Jezler concluded the Takata-Ara reaction was a result of dysfunction of the liver, dependent on the colloidal composition of the serum. Jürgens, from experiments on geese and dogs, concluded that the test was dependent on metabolic products of damaged liver cells, and Crane suggested as possible causes of a positive reaction: (1) release of liver proteins into the circulation (that is, in cases of yellow atrophy); (2) inability of the liver to alter proteins contained in the blood; and (3) failure of some blood to pass through the liver, going instead, by way of collateral venous anastomoses, directly into the general circulation.

Another suggestion has been made by Reeht, that lipoids played an important role in the test.

Wuhrmann and Leuthardt held that the precipitate was due to the linkage of sublimate with proteins of the blood serum in which fibrinogen also played a part; others have suggested that fibrinogen played some role in the reaction.

One of the few papers based on animal experimentation on the subject is by Hahn, who made mixtures of calf and beef blood so as to obtain different albumin-globulin ratios. He concluded that as the ratio of globulin to albumin increased, results of the Takata-Ara test became more positive. Wayburn and Cherry have summarized their views as follows:

"It is extremely difficult to explain the occurrence of the positive Takata-Ara reaction by any one hypothesis. Increase in the globulin fraction of the serum, both relatively and absolutely, does occur in the majority of the cases, but there are many cases in which it does not. Conversely, there are many cases with changes in the globulin without positive Takata reactions. The presence of liver damage as such appears to play very little role. If the release of liver proteins into the circulation were important, acute yellow atrophy should give uniformly strongly positive reactions, but it does not. If the reaction were caused by the failure of blood to pass through the liver, portal thrombosis should give uniformly positive reactions, but it does not. It seems rational at this time to be content with Staub and Jezler that the Takata reaction represents a dysfunction of the liver. It probably is dependent on the colloidal composition of the serum. It probably represents some retention substance which under the usual conditions of its occurrences requires some time to be formed in sufficient quantity to result in a positive reaction (comparable, again, to an elevated blood urea in chronic glomerular nephritis). It is possible that this is a toxic product."

The main objection to this summary is their agreement with Staub and Jezler and the suggestion that the reaction is due to a toxic or retention substance. Greene, and others as well, have pointed out that the results of the test

are often positive when the liver is not damaged to the extent that any other tests or observations can demonstrate such damage and also are positive in diseases in which there is no indication the liver is involved.

The reaction is likely to be due to a more fundamental change in the body fluids, which often, perhaps more often, is due to dysfunction of the liver than to that of any other organ but which may be caused by the dysfunction of other organs, and results in colloidal changes in various bodily fluids, such as serum, spinal fluid, and the fluids secreted by serosal surfaces.

RESULTS OF OBSERVATIONS

In order to investigate the value of the Takata-Ara reaction, the two series of cases which I have studied have been combined, since a separate examination of each series did not reveal any particular differences. The results in the first series have been reported previously, and this series consisted of 86 consecutive cases. In all but one instance the bromsulfalein test was performed simultaneously, and in all but three, qualitative and quantitative van den Bergh reactions were studied. Furthermore, examinations of the serum protein were made in 62 of these cases. All these patients were carefully examined by experienced clinicians, with special reference to the possibility of disease of the liver. The condition of the liver of 27 of these was observed either at operation or at necropsy. The method of performing the test was the six-tube method suggested by Heath.

Since study of the second series was stimulated by the criticism of Wayburn and Cherry, their technique of using eight tubes was followed. The cases in this series were selected in an entirely different manner from that used for selection in the first series. Only cases were included in which the bromsulfalein test indicated retention of 6 per cent or more (grade 1) of dye; the Takata-Ara test was performed on the same sera. All these patients had both qualitative and quantitative van den Bergh reactions. In this series the livers of 50 patients were observed either at operation or at necropsy, and all the patients in the series, like those of the former series, were studied carefully by clinicians, with particular reference to the possibility of disease of the liver.

The combined series included 249 patients. The condition of 72 of these patients was diagnosed as cirrhosis of the liver; of this number, 43, or about 60 per cent, had a positive Takata-Ara reaction (Table II). Thirty had malignant disease involving the liver; of these, 12, or 40 per cent, gave positive Takata-Ara reactions. The livers of 108 patients were involved in other types of disease, of which 20, or 19 per cent, gave positive Takata-Ara reactions. In all, there were 210 cases of clear-cut involvement of the liver, in 75, or 40 per cent, of which Takata-Ara tests gave positive results. When the cases of cirrhosis of the liver were omitted, positive reactions were found in 23 per cent of the other cases in which the liver was involved. Eighteen patients in the second series had more or less acute hepatitis, and 5, or 28 per cent, of these gave a positive Takata-Ara reaction. In this series, which obviously was selected in favor of involvement of the liver, positive Takata-Ara reactions were noted in 5 instances in which there evidently was no involvement of the liver; results of

the Takata-Ara test were negative in 12 cases in which obviously the liver was not injured. In this series, as in some reported by others, obstructive lesions did not result in positive reactions, and in all kinds of early lesions of the liver the results of the tests were usually negative.

TABLE II

TAKATA-ARA TEST AS RELATED TO LIVER DAMAGE. FIRST AND SECOND SERIES COMBINED (249 CASES)

CONDITION OF LIVER*	TAKATA-ARA TEST			
	POSITIVE		NEGATIVE	
	CASES	PER CENT	CASES	PER CENT
Cirrhosis present	43	60	29	40
Cirrhosis absent	41	23	136	77
Malignancy of liver	12	40	18	60
Liver involved†	20	19	88	81
Liver not involved	3	23	30	77

*There were 210 cases in which the liver was involved; in 75, or 36 per cent, the results of the Takata-Ara test were positive. When the cases of cirrhosis are omitted, the Takata-Ara test was positive in 23 per cent.

†Other than diseases listed above.

TABLE III

TAKATA-ARA TEST OF LIVER FUNCTION IN FIRST SERIES (86 CASES)

RESULTS OF VARIOUS TESTS	TAKATA-ARA TEST	
	POSITIVE	NEGATIVE
Albumin-globulin ratio, reversed	12	2
Albumin-globulin ratio, normal	9	39
Bromsulfalein test, positive	28	29
Bromsulfalein test, negative	4*	24
van den Bergh reaction, direct	22	19
van den Bergh reaction, indirect	9†	33

*Liver apparently not involved.

†In 4 of these cases the liver apparently was not involved.

There was no evidence to suggest that changes in the total protein of the serum could be correlated with the Takata-Ara tests; this was studied in the first series in particular (Table III). In 12 cases in which results of the Takata-Ara test were positive, there was a reversal of the albumin-globulin ratio, and in 9 there was a normal ratio; in 2 cases the ratio was reversed, but results of the Takata-Ara test were negative. In only about one-half of the cases in which there was a reversal of the albumin-globulin ratio was the liver involved, and in 9 out of 21 cases of cirrhosis the ratios were reversed (Table IV). In only one case, that of hypernephroma, the ratio was reversed, and involvement of the liver was not diagnosed. It should be noted, however, that very few cases of disease of the kidney were included in this series. It is possible that the fibrinogen content of the serum has an influence on the Takata-Ara reaction and may account for Takata's⁷⁵ reaction in cases of pneumonia.

The correlation between the Takata-Ara test and the bromsulfalein test was not high. In only half of the cases of the first series in which retention of dye occurred were the results of the Takata-Ara tests positive. Since the second series included only cases in which retention of dye of some grade was present with the exception of a single case, the correlation can be examined only from one side. Of 163 cases 51 gave a positive Takata-Ara reaction.

TABLE IV

ALBUMIN-GLOBULIN RATIO IN DISEASE OF LIVER IN FIRST SERIES

CONDITION OF LIVER	ALBUMIN-GLOBULIN RATIO	
	NORMAL CASES	REVERSED CASES
Cirrhosis present	12	9
Cirrhosis absent	36	4*
Cells of liver involved	23	13
Cells of liver not involved	25	1†

*Carcinoma of liver present in 3 of these cases, hypernephroma in the fourth.

†Hypernephroma.

The van den Bergh reaction was indirect in a large number of instances in which the Takata-Ara reaction was positive. In the present series direct van den Bergh reactions were present when results of 27 Takata-Ara tests were positive and when 23 were negative.

Ten patients in the present series had syphilis, 7 of whom gave positive results to the Takata-Ara test. The liver was involved in all of these patients.

TABLE V

COMPARISON OF TESTS OF LIVER FUNCTION IN FIRST SERIES

TEST AND RESULT	CELLS OF LIVER	
	INVOLVED CASES	NOT INVOLVED CASES
Takata-Ara test, positive	28	4*
Takata-Ara test, negative	25	29
Bromsulfalein test, positive	51	3†
Bromsulfalein test, negative	2‡	29
van den Bergh reaction, direct	39	2§
van den Bergh reaction, indirect	13	29

*Cases of myocardial degeneration, adenoma of gall bladder, hemolytic icterus, and polythemia, respectively.

†Cases of arthritis, hypernephroma, and facial neuralgia, respectively.

‡Hepatitis (?) and syphilis present in one case; recession in cholangitis in the other.

§Hypernephroma in one case, hemolytic icterus in the other.

As was pointed out in a previous paper, the results of the bromsulfalein test were extremely significant. In the first series, results of the bromsulfalein test were positive in 51 cases in which the liver was involved by disease, and in only 3 cases in which the liver was thought to be uninvolved (Table V). Even in these 3 cases, however, there may have been some involvement of the liver. In the present series there were 12 cases in which no clinical diagnosis of involvement of the liver was made, but it is interesting to note that in 5 of these the diagnosis of gout was recorded. Since an increase in uric acid in the blood is present in gout and since Bollman, Mann, and I have shown that the liver is involved in the metabolism of uric acid, the livers of these patients may not have been normal and the retention of dye may have been valid. In 2 cases there were malignant lesions of other organs.

Again the importance of retention of dye of low grade, up to 12 per cent retention, is brought out, since in a large number of cases of involvement of the liver retention of dye grade 1 was present (Table VI). There were in the present series 9 cases of Banti's disease, and in 6 of these Takata-Ara reactions were positive. This is in contrast to the experience of Wayburn and Cherry, who stated that in their series of 3 cases of Banti's syndrome and 2 of splenic

and portal thrombosis the results of the Takata-Ara test were consistently negative. In one case of multiple myelomas the Takata-Ara reaction was positive but there was no retention of dye.

TABLE VI

TAKATA-ARA TEST, BROMSULFALEIN TEST AND VAN DEN BERGH REACTION IN PRESENT SERIES

CONDITION	CASES	BROMSULFALEIN TEST GRADE				VAN DEN BERGH REACTION			
						DIRECT	INDIRECT	LESS THAN 2 MG. PER 100 C.C.	MORE THAN 2 MG. PER 100 C.C.
		1	2	3	4				
TAKATA-ARA TEST NEGATIVE									
Hepatitis	13	4	6	3	0	8	5	10	3
Malignant lesion of liver	16	3	3	9	1	5	11	14	2
Cirrhosis	20	9	7	1	3	3	17	16	4
Other diseases	62*	37	20	5	0	7	55	58	4
TAKATA-ARA TEST POSITIVE									
Hepatitis	5	0	1	2	2	5	0	1	4
Malignant lesion of liver	5	2	3	0	0	1	3	3	2
Cirrhosis	27	5	6	13	3	17	10	16	11
Other diseases	15†	1	5	7	1	4	12	14	1

*In 12 of these cases no clinical diagnosis of involvement of the liver was made, but in 5 of them a diagnosis of gout was made.

†In one of these no clinical diagnosis of involvement of the liver was made and the bromsulfalein test gave negative results; in 4 other cases also no involvement of the liver was found.

COMMENT

From an examination of the literature, as well as from my own series of cases, it becomes evident that the Takata-Ara reaction has not been explained on any absolute basis.

It is, therefore, an empiric test. A wide variety of explanations have been offered to account for the reaction, and different explanations of its chemical or physical mechanism have been defended. The evidence supports the conclusion that in a high percentage of positive reactions the albumin-globulin ratio is reversed and that in even a higher percentage there is some alteration in either the relative or the absolute amounts of these proteins. On the other hand, the role of fibrinogen, as well as that of other contents of the serum, has not been investigated thoroughly. Important are the observations that in an appreciable number of cases the albumin-globulin ratio is not disturbed when the Takata-Ara reaction is positive; this indicates that some other factor or factors must be present to explain the phenomenon.

It is more than evident that the test is not specific for cirrhosis of the liver. For the conditions the test was first proposed to diagnose there is no reason to believe that it has any value. It is evident enough that a large number of patients with cirrhosis will have positive reactions, and the more extensive the cirrhosis and the longer the disease has lasted, the more likelihood of obtaining a positive reaction. The degree of positiveness of the test is not indicative of the degree of hepatic injury, and it is evidently clear that fine laboratory subdivisions of readings of the test will only confuse the clinician. In spite of the

fact that a positive result of the test may be expected in 82 per cent of cases of cirrhosis, it cannot be assumed that given a positive reaction such a diagnosis is confirmed. This, of course, is because a positive reaction occurs in so many other conditions. Jankelson, Segal, and Aisner reported that the Takata-Ara test gave about the same percentage of positive results, namely 80, in cirrhosis as did their tyrosine test. If it were desired, however, to consider the test as a general test of liver function, the results would be disappointing. It certainly will not compare favorably with either the bromsulfalein test which, when properly performed,* will indicate roughly 95 per cent of cases with hepatic injury, or the van den Bergh test. If a direct van den Bergh reaction is used as a criterion of injury to the liver, it will be found to be reliable in about 80 per cent of cases. One may expect only about 1 per cent of cases to yield a direct reaction in the absence of clinical evidence of hepatic damage if careful ring tests are performed. Indirect van den Bergh reactions will occur until the damage to the liver is great enough to render the organ unable to excrete the changed bilirubin through the bile passages.

The question may be reasonably asked if the Takata-Ara test can be used to denote intrahepatic injury as distinguished from extrahepatic pathologic changes, with subsequent effects on the liver, or at least on the biliary system. A fair appraisal would suggest that the test is about as valuable as some of the proposed tests for this purpose. Unless obstruction has been present for a long time, a negative result will be obtained. Unfortunately, unless the parenchymal damage is severe or moderately severe, the test also gives negative results, and this means the test is least useful when most desired. Judiciously used as a differential test between acute hepatitis with jaundice and obstruction of the bile ducts, the test should prove of value, although not entirely accurate.

Investigators must not lose sight of the fact that the Takata-Ara test may be positive and often is in many kinds of diseases in which the liver may not be involved, as for example, syphilis, nephritis, pneumonia, and pulmonary tuberculosis. If there is a substance in, or a condition of, the serum common to the wide variety of diseases which yield positive results to the test, its nature has not been elucidated.

It is unlikely the test would ever have enjoyed such widespread discussion if the technique had not appeared to be easy. Indeed, most authors have praised the simplicity of the test, as if that made up for its shortcomings. If the test is so simple, why have so many modifications arisen in fifteen years and such divergent results been obtained by different authors? Bots listed fourteen modifications and, incidentally, recommended the one of Jezler,⁴² who wrote that it was not so much a matter of the particular method used but the interpretation of the test. The truth of the matter is that the test, which is empiric, of unknown mechanism and colloidal in nature, is not simple either to perform or to read. The strictest attention to details is necessary, and even faulty preparation of glassware can be a frequent source of error. The reading of such a test as the Takata-Ara requires experience in a wide variety of similar procedures and should not be attempted by a novice. Even after the correct reading is

*The dose should be 5 mg. per kilogram of body weight, and the lowest grade of retention of dye to be considered positive should be 6 per cent at the end of one hour.

made, its interpretation is still a matter for the most experienced, for after fifteen years there is no agreement as to the degree of flocculation necessary or the number of tubes involved to constitute a positive result. No wonder its true value has not been established.

Some investigators have maintained the test was of value in prognosis, recording correlated shifts in the test as patients improved or became worse. The fact that the test often gives negative results in early cirrhosis and positive results in late cases at once indicates the rationale of such a suggestion. There is not enough information about the matter as yet to form any definite conclusion about the prognostic value of the test, but from my own experience I would expect it to follow changes in the condition of the patient rather than to precede such changes, so that although it would in a general way parallel the patient's condition, it could not be used often to predict the course of events in any given case. Gertler and Lachenicht contended that a positive test was an important prognostic sign, and once a patient has a positive test he does not often completely recover from his malady. It is doubtful whether it will surpass the van den Bergh as a prognostic test.

Much evidence supports the view that the Takata-Ara test is not very sensitive. Hence, there is no need to perform the test if the bromsulfalein test gives negative results. If results of the dye test are positive and a Takata-Ara test is then performed, a positive reaction will usually indicate a severe grade of parenchymatous damage, and this may help in the diagnosis. If the result of the test under this circumstance is negative, the chance that the patient has cirrhosis is lessened and here it may render a definite service.

SUMMARY AND CONCLUSIONS

The Takata-Ara test is an empiric one and may give positive results in a wide variety of diseases, in particular, parenchymatous diseases of the liver, pulmonary tuberculosis, and nephritis. It is not very sensitive.

It is not a specific test for any one disease, but it usually gives positive results in cirrhosis of the liver, especially when the disease has progressed to moderate severity. The reaction is frequently positive in acute hepatitis and in malignant disease of the liver.

The test is correlated to a great extent with changes in the ratio of serum albumin to globulin, but the correlation is not absolute and the mechanism and cause of the reaction remain unexplained.

It has some slight value in prognosis, but its true significance in this field has not been established. It appears to have greater value in establishing the general nature of an hepatic injury—whether it is of extrahepatic or intra-hepatic origin—although more information in this regard is needed.

The many modifications of the technique of the test and different methods of interpreting its results not only make the performance of it confusing, but also cast great doubt on the oft-repeated statement that the test is a simple one.

If the test is to survive there is great need for the establishment of a standard procedure based on a long and varied experience with the test. A careful reading of the literature, however, does not suggest that it would be worth the effort.

A DISCUSSION OF ELECTROPHORESIS WITH SPECIAL REFERENCE TO SERUM AND ALLERGENS*

H. A. ABRAMSON, M.D., AND D. H. MOORE, PH.D., NEW YORK, N. Y.

RECENT developments in the methods for the separation of proteins by the moving boundary technique have extended the field of electrophoresis to so great an extent that any attempt to treat the data comprehensively in a short article would be unsatisfactory. We shall, therefore, here outline briefly the theory of electrophoresis, its history, method, and some of its usefulness in studying the components of serum and of ragweed extracts.

ELECTRICAL CHARGE OF PROTEINS

The most striking characteristic of the electrical polarity of protein molecules and protein surfaces is the fact that there are large numbers of amino and carboxyl radicals which act as if they were on the surface.¹ These groups, that is, the COO^- and NH_3^+ groups, serve to determine the net charge of the protein under ordinary conditions. Thus, since protein molecules carry electrical charges, they will migrate when subjected to an electrical field, the direction and velocity depending upon the sign and quantity of the net charge. The molecule is constantly taking on and giving up hydrogen ions, so that the instantaneous charge is a small integral number; but the statistical nature of the charging process allows the time average of the resultant charge to be fractional. Thus, if hundreds of ions are going on and leaving a molecule every second, the instantaneous net charge may be 1, 2, 3, 4, 5, 6, or more whole charges, but the statistical result may be fractional. The surface of the protein molecule is so large and the dissociation constants of its amino acids are so close together that each protein ion acts as if it bore a fractional charge when its mobility in an electrical field is observed. It is quite correct to state, for example, that under given conditions an egg albumen ion may have a net charge equivalent to 4.53 electrons. The fractional nature of the net charge on these large ions makes possible a wide variety of electrophoretic identifications at a given pH.

ISOELECTRIC POINT OF PROTEINS

Whenever the sum of the negative charges on a protein molecule is equal to the sum of its positive charges over a time average, the net charge is zero and the electrical mobility is zero. The protein or the protein surface is called isoelectric. The isoelectric point, therefore, is most difficult to determine directly. At best it can be determined accurately only by interpolation, because

*From the Electrophoresis Laboratory and the Department of Physiology, Columbia University, and the Medical Service of Dr. George Bachr and the Laboratories of the Mount Sinai Hospital, New York.

This investigation has been aided by a grant from the Josiah Macy, Jr., Foundation.

methods for determining the isoelectric point directly are not sufficiently sensitive to show the small movement which, for example, would be given by a net charge equivalent to 0.01 electron.

One frequently finds the expression "isoelectric range" in connection with proteins like insulin and casein. Although the zone of insolubility of casein may extend over a wide pH range, its isoelectric point, as well as that of insulin, is sharp. Indeed, the rate of change of the electrical charge or of the electric mobility with pH is not accurately represented by the insolubility curve in the zone of the isoelectric point. It lies *somewhere* near the center of this curve, but calculations designed to determine the isoelectric point of proteins from the zone of insolubility are difficult. The isoelectric point should be taken directly from mobility-pH curves. The term "isoelectric range" and similar expressions should be replaced by the "zone of insolubility near the isoelectric point" or similar expressions which refer to the experimental technique used to determine physical characteristics of the protein in question.

EARLY EXPERIMENTS ON SEPARATION

As long ago as 1912 Michaelis and Davidsohn² found that the isoelectric point of hemoglobin under certain conditions was pH 6.8. This point was unaffected by the addition of 1 per cent of serum albumin to the hemoglobin solution; that is, each protein migrated essentially independently of the other. The fact that proteins may exist in solution independent of one another and irrespective of the values of their net charge is well borne out by the behavior of proteins in serum. Aside from these early experiments of Michaelis little attention was given to this aspect of protein chemistry up to the work of Tiselius in the last decade.³ Speaking generally, mutual precipitation of charged colloids is observed only when at least one of the substances is easily precipitated by electrolytes. In harmony with this, Tiselius found that mixtures of proteins of opposite sign and of great difference in net charge were usually stable, although this was not always the case. Tiselius studied the effect of Bence-Jones protein on phycoerythrin and found that the change in the electrical mobility of the two proteins in mixtures was not marked, although their charges were of opposite sign. Using ultraviolet photography to bring out the boundary of the protein in a U-tube of somewhat conventional design, Tiselius found that the boundaries of uniform proteins in their artificial mixtures were reasonably well defined. Since these early experiments by Tiselius have been definitely superseded by his own experiments and by those of investigators who have used his technique, they will not be cited in detail here. The reader interested in the history of the subject should read the appended references.⁴⁻⁶

We must not forget that the microscopie method of electrophoresis may also be used to separate particles having different electrical charges.⁷ Thus, one of us (H. A. A.) has been able to distinguish between the blood cells of different animals using the method of electrophoresis and has repeatedly studied the purity of crystalline precipitates by examining their suspensions in the microelectrophoresis cell. By this method insoluble impurities which have different electrical mobilities may be readily observed. In particular may be mentioned the

gradually a plunger by means of a clockwork into the buffer tube toward which the migration is progressing, or by flowing fresh buffer into the same buffer tube with a mechanically controlled syringe. This tends to raise the level of the liquid on the same side, and since the system seeks hydrostatic equilibrium, there is a flow through the U-tube to the other side. A modification in which one buffer tube is closed has been used.¹⁰ In this case compensation is achieved by forcing buffer either into or out of the closed side.

A single-sectioned tall cell suggested by Tiselius and used in this laboratory (Columbia), schematically shown in Fig. 2, effectively increases the length of the U-tube. The components can migrate the whole length of the tube instead of only half of it, as in the case of the divided cell (Figs. 1 and 4). The bottom section and one leg are filled with the protein solution, while the other leg is filled with buffer. The absence of the middle plates allows complete visibility, so that no boundaries may be obscured. This cell is used only for analytical purposes and not for recovering separated material.

Fig. 3.—*a*, Three component mixture in a horizontal system; *b*, an electric field has acted on the three component mixture.

Before discussing the optical method adapted by Tiselius for observing colorless boundaries, the electrophoresis of a three-component mixture will be considered. In Fig. 3*a* let the three horizontal lines be a mixture of proteins in a horizontal system (for simplicity), forming boundaries with the buffer solution at points marked *B* and *B'*. Let protein *p* have an electrical mobility of one unit, protein *p'*, two units, and *p''*, three units. Let a uniform electric field be applied. After a given period the components will be moved to a position shown in Fig. 3*b*. It is evident that by making a segregation at *Y* and at *B*, a portion of *p* and of *p''* can be obtained in pure form. It is observed, however, that at different points in the system there will be mixtures of *p* and *p'*, *p*, *p'*, and *p''*, and *p'* and *p''*, and that *p'* cannot be obtained in pure form at all. If one starts with the three constituents in a U-tube instead of a horizontal tube, the same phenomena occur. In Fig. 4, *a* shows the protein solution before migration has begun; *b*, after the components have begun to migrate; and *c*, after compensation has pushed the boundaries to the ideal position for separating pure *p* and pure *p''*.

The visualization of colorless boundaries was accomplished in the following way: Advantage was taken of the fact that wherever there are differences

of concentration of protein in solutions there will be a refraction gradient, because the greater the concentration of protein the smaller the velocity of light. Deflection of light passing through these zones of refraction gradients may be detected by an adaptation of an old method of observing defects in telescope lenses. A boundary with sufficient protein acts as if it were a defect in the lens system, and these defects may be photographed and the position of the boundary may thus be marked. In addition, by suitable optical equipment, the concentrations of the materials forming the boundary may be obtained.

Fig. 4.—*a*, The protein solution before migration has begun; *b*, after the components have begun to migrate; *c*, after compensation has pushed the boundaries to the ideal position for separating pure *p* and pure *p*."

Fig. 5.—Diagram illustrating method of detecting defective spots in lens by means of an opaque, exploring diaphragm. In practice the exploring diaphragm intercepts the deviated rays. For explanation see text.

The optical basis of the schlieren or streak method is described in great detail in many places and suitable references are appended.¹¹ It is dependent upon a method of Foucault,* who devised an accurate technique to test lenses

*This method was originally used by Foucault to test telescope mirrors.

for chromatic and spherical aberration. Foucault employed light from a distant source which he brought to a focus by the lens to be tested (Fig. 5). A diaphragm is placed so that it just covers the image formed at f , the focal point of the lens. An observer looking through a telescope behind the diaphragm and focusing on the lens observes only the rays which fail to converge to a single point at f . These rays which do not strike the diaphragm come from defective portions of the lens and their position is imaged in the telescope. This procedure was reversed by Toepler who by intercepting the deviated rays made the defective portion of the lens appear dark in the telescope. The present method used for detecting concentration gradients in the electrophoresis cell is an adaptation by Tiselius of the Toepler method. If the lens is replaced by the protein solution, the protein gradients at the boundaries appear as defects, giving dark bands where the boundaries occur. Of course, there must be a converging lens (schlieren) just behind the cell containing the solution to bring the rays to a focal point. The walls of the cell, the converging lens, and telescope lens must be without defects in order to have true representation of the boundaries.

APPLICATION TO SERUM PROTEIN

The history of the analysis of serum contains numerous attempts to fractionate serum into constituent proteins ever since serum albumin was crystallized by Guerber.²² Although serum could be separated into several fractions which had different solubilities, these fractions did not fulfill the criteria required to establish them as chemical individuals. Thus Sørensen conceived of serum as a system composed of reversibly dissociable components. Indeed, it was felt that many fractions isolated from serum may have been the results of the treatment of the serum during their isolation. Recently Block²³ came to the conclusion that "serum does not contain several independent proteins. The fractions isolated by physical chemical methods are not pre-existent in serum but result from the technique employed." Although the ultracentrifuge (Svedberg and others) gave much valuable information regarding the nature of serum and its proteins in normal and pathologic conditions, it remained for Tiselius to provide a simple means of attack capable of removing the fractions of serum protein after their separation. It was found, using the method of Tiselius, that serum placed in an electric field without preliminary salt precipitation separates into zones of different electrical mobilities. These components could be isolated and were homogeneous in behavior. In Fig. 6 serum albumin is observed to have the greatest electrical mobility, and instead of two globulins as were commonly supposed to exist in serum, three globulins are found. These are called alpha, beta, and gamma globulin in the order of their electrical mobilities. Similar patterns are observed in horse, human, rabbit, and other sera. In order to get the most clear-cut results, the experiments are performed with serum diluted approximately three times. Once isolated by electrophoresis, the separate constituents of serum exhibit electrical mobilities which are essentially the same as those found in the serum itself. This is important evidence that the individual constituents are present in the serum and does not support the theory that serum is a continuous mixture.

NORMAL AND PATHOLOGIC SERUM

A comparison of the protein composition of normal and pathologic sera has been made by Longworth, Shedlovsky, and MacInnes, as well as by others using the technique of Longworth.¹⁴ In Fig. 6 are shown their electrophoretic diagrams of normal serum and sera of patients with pneumonia, peritonitis, rheumatic fever, peritonsillar abscess, and acute lymphatic leucemia. It will be noticed that all of these diseases exhibit an increase in globulin as determined by the areas under the curves representing the different proteins.

Fig. 6.—Longworth diagrams showing the various constituents of sera in different diseases. These diagrams are copies of similar illustrations published by Longworth, Shedlovsky, and MacInnes.

ELECTROPHORESIS OF ANTIBODIES IN ALLERGY

Newell, Sterling, Oxman, Burden, and Krejci¹⁵ have separated antibodies from allergic serum by the method of electrophoresis. Euglobulin and pseudoglobulin prepared by the older methods are mixtures of globulins isolated by electrophoresis. Euglobulin is essentially the beta and gamma globulin, while pseudoglobulin consists of alpha and gamma globulin. Antibodies, in general, have been found particularly in the pseudoglobulin fraction of the serum corresponding to the alpha and gamma fractions. This was found to be the case for the skin-sensitizing antibody by Sherrer¹⁶ and by Stull, Glidden, and Lovelless¹⁷ by fractional precipitation of pseudoglobulin. Newell and co-workers kept

their serum as concentrated as possible and dialyzed for two days against physiologic saline containing 0.02 M phosphate for buffer. The pH was about 8.1. By collecting and analyzing the separated gamma and beta globulin, it was found that the skin-sensitizing antibody was in the gamma globulin fraction of serum. To check these results serum fractions were examined, using similar techniques for antitoxin against staphylococcus hemolysin. In eight experiments the antitoxin was found only in those fractions which contained gamma globulin. The distribution, therefore, was the same as for the skin-sensitizing antibody.

Sera from three rabbits which had been sensitized by Newell and others with alum-precipitated ragweed extracts were cooled and tested for the precipitin reaction with concentrated ragweed solution. The supernatant liquid, following precipitation, was separated in the Tiselius apparatus, and the upper positive and upper negative fractions were tested against ragweed dilutions. Tests showed that the gamma fraction contained an antibody to ragweed, whereas the upper positive arm contained the faster moving albumin, alpha and beta globulins which were inactive. In rabbits, therefore, it was concluded that the antibody for ragweed is in the same protein fraction as that found by others for anti-egg albumen antibodies.

ELECTROPHORESIS OF ALLERGENS

Extracts of pollen allergens are colored solutions containing pigment and biologically active factors, the nature of which has not as yet been accurately determined because monodisperse systems have not been isolated; that is, there is no evidence that the single chemical substances responsible for hay fever have been isolated as yet by chemical methods. By electrophoresis, however, it is possible to come closer to a solution of the problem. Early experiments to determine the electrical nature of the active constituents of ragweed extract were published some time ago. It was found that the isoelectric point of quartz particles treated with freshly dialyzed ragweed solution was at pH 3.9, with this point shifting to pH 4.3 as the solution stood. At the same time experiments were begun using the conventional moving boundary method to study the electrical charge of the pigment, and to isolate, if possible, the biologically active constituent. With the development of the Tiselius technique the new method lent itself admirably to the separation problem. In Fig. 7, *a* is a diagram obtained by the Tiselius method and the Longworth scanning technique. The US (unpigmented, slow) peak¹⁹ is a colorless constituent which is highly skin reactive. Note in Fig. 7*b* that minor pigmented fractions are present which migrate with velocities faster than the dominant US fraction. The US fraction is highly skin reactive and in certain experiments on skin reactive individuals a solution containing 0.0003 mg. of protein nitrogen per cubic centimeter gave a positive scratch test. Recent unpublished experiments (Fig. 7) with H. Gettner have disclosed that even better fractionation may be obtained using undialyzed extract. We wish to report here in a preliminary way on these experiments. Longworth patterns obtained with the Tiselius technique of undialyzed giant ragweed extract indicate that the colorless constituent previously reported is a dominant probably monodisperse material.

The isoelectric point of this material, as well as the mobility, apparently vary with pH very much the same way that the ragweed covered quartz particles did in the earlier experiment. These data will be reported elsewhere.

The electrophoretic analysis of the pollen extract opens an interesting field for research. It is desirable that the grass pollens be investigated as soon as possible to ascertain whether the immunologic specificity which overlaps among the grasses also is manifested in the chemical behavior of the biologically active constituent separated by the electrophoretic method.

Fig. 7.—*a*, Electrophoretic pattern obtained with undialyzed ragweed extract. The major constituent is an unpigmented, slow moving (US) fraction which is also observed in dialyzed extracts. The gradation in shading depends upon the presence of pigments. Note the absence of pigment where the US fraction is being left behind by the pigments which migrate more quickly.

b, Another sample of undialyzed ragweed extract after one hour and thirty minutes. Electrophoretic pattern to illustrate presence of four pigments in a sample of undialyzed ragweed extract. The US fraction is the major component on the extreme left. Four minor components, faster moving pigments, are found at the lower part of the pattern. In general, six pigments may be observed.

The fractionation of ragweed pollen lends itself to further study of antigen-antibody reaction in atopic sera; that is, it would be of interest to investigate in detail the reaction of the US fraction, as well as the pigment fractions, with allergic sera to see whether the results obtained by Newell and co-workers with crude ragweed extract may be confirmed. It is conceivable that the presence of pigments inhibits or alters an allergen-reagin reaction.

Preliminary data obtained with the US fraction in the ultracentrifuge indicate that its molecular weight is low, probably less than 10,000.

SUMMARY

The nature of the charging process of protein molecules leads to statistical values of the net charge. The large number of differences in the value of the net charge makes the electrophoretic technique desirable for purposes of separation of proteins from one another. This procedure has been greatly improved by the development of the Tiselius moving boundary technique. The applica-

tion of the Tiselius technique to a study of the components of sera, to the properties of allergic antibodies, and to the fractionation of ragweed pollen extract is briefly outlined.

RECENT PROCEDURES APPLICABLE TO PROBLEMS IN LIPID METABOLISM

H. C. ECKSTEIN, M.S., PH.D., ANN ARBOR, MICH.

DURING the existence of this JOURNAL abundant evidence for the fact that progress in clinical investigations often follows advancement in analytical procedure has been presented. It seems fitting, therefore, in contributing to this, the Silver Anniversary Number, to call attention to some of the newer methods of attack applicable to studies in lipid metabolism.

The early issues of this JOURNAL contain accounts of the current methods for lipid analysis. While considerable information was obtained as a result of the use of these procedures, the knowledge gained was nevertheless incomplete because of the shortcomings of the particular methods employed. The importance of the phospholipids in fatty acid transport was demonstrated, and while it was suspected that one of these, lecithin, probably played a more important role than the others, such a conclusion was not warranted because at that time the available method was limited to the determination of the total phospholipids only. Nevertheless, it was usually stated that lecithin was the vehicle most intimately concerned in this transport. In addition to this, no method was available for the direct determination of the small amounts of neutral fat of the blood, nor was it possible to ascertain the nature of the acids combined with neutral fat or cholesterol. Recent advances have been made which should assist in the clarification of these problems.

Three methods have recently been described whereby a very satisfactory fractionation of the phospholipids of the blood can be accomplished. These methods are of such a nature that it is not necessary to employ a highly trained chemist for their use, since with some practice they should be handled by the well-trained laboratory technician. The methods are similar in that in each case a quantitative determination of choline is made. Lecithin and sphingomyelin contain approximately equal amounts of this base, whereas none is present in cephalin. Thus by determining total phospholipids and choline the cephalin content can be calculated. Williams and co-workers,¹ as well as Kirk,² rely on the insolubility of sphingomyelin in moist ether for its determination, whereas Thannhauser and others³ precipitate the compound with Reinecke's acid. These are distinct advantages over the older procedures which depended entirely upon fractionation with various fat solvents. On the whole, the Thannhauser procedure seems to be the most desirable of the three because of the direct determination of the sphingomyelin, but it requires as much as 60 c.c. of plasma or cells. A micromethod, based to some extent on the Thannhauser procedure, has been developed in the Research Laboratory of the Children's Fund of Michigan. This procedure should be in press in the near future and should be a valuable contribution, inasmuch as only 3 c.c. of plasma are required. Thannhauser has

reported that the sphingomyelin content of normal human serum comprises about 10 per cent of the total phospholipids, while cephalin³ and lecithin are present in approximately equal amounts (45 per cent). Data on pathologic blood specimens have as yet not been reported, but the method has been successfully applied to normal human organs.⁴ As Thannhauser points out, "It will be of interest to observe whether the values for the various phospholipids vary in their proportion in organs under pathological conditions, especially in so-called fatty degeneration." Very recently Artom and Freeman,⁵ using a procedure consisting of a combination of the Kirk and Thannhauser methods, determined the individual phospholipids in the plasma of rabbits after a fatty meal and observed that a definite increase in the total phospholipids was only occasionally observed. When this took place, higher values for lecithin were generally in evidence, but lower cephalin values were usually encountered when the fat was fed. These data indicate that lecithin was the only phospholipid concerned with the transportation of the fatty acids. The old view that this was the case now rests on a more secure foundation.

In the past the blood phospholipids had been assigned another important role. In 1919 Meigs, Blatherwick, and Cary⁶ proposed that these lipids were the precursors of the fat of milk. At that time this appeared to be an attractive theory, but reinvestigations of the problem by others⁷ threw much doubt upon the proposal. Recently the application of a newly developed method for neutral fat, originated by Voris, Ellis, and Maynard⁸ has offered support to an alternate and more tenable view. Blood was taken from the subcutaneous abdominal vein and iliac artery of the lactating cow and analyzed for neutral fat. The results obtained indicate that a removal of neutral fat takes place during the circulation of blood through the active mammary gland. This fraction of the blood lipids thus contributes to the formation of milk fat. The gland itself must, however, also contribute to this phenomenon, since the simple removal of neutral fat from the blood stream cannot account for the peculiar composition of fatty acids of low molecular weight. As is the case with the other procedures discussed, the method has only been applied to a small extent, but it should prove to be very useful in the future.

Another recent procedure which should have great possibilities is one devised by Kelsey⁹ for determining the fatty acids in the different blood lipid fractions. The phospholipids are removed by precipitation with acetone, and residual lipids are digested with a lipase obtained either from pancreas that had previously been treated with ammonia in order to destroy the cholesterol esterase, or from the castor bean. Under such conditions only the neutral fat is split and the fatty acids thereby liberated can be isolated. Those acids combined with cholesterol can be freed by saponification. Few applications have as yet been made of the procedure, and some trouble has been encountered in its application to the blood. This difficulty will probably be overcome. The future should bring valuable information from the use of the method, thus increasing our knowledge of the types of fatty acids transported by the different constituents of the blood lipids under normal and abnormal conditions.

Some of the most valuable data on lipid metabolism have recently been obtained as the result of the use of isotopes or radioactive elements for labeling substances synthesized or formed in the normal living organism. Outstanding in the use of deuterium, the isotope of hydrogen, are the investigations of Schoenheimer and his associates, whose work has recently been reviewed.¹⁹ These investigators have clearly demonstrated that a continuous synthesis of cholesterol and fatty acids takes place in the animal organism. In following the fate of various labeled fatty acids, it was demonstrated that those of low molecular weight disappeared almost explosively, whereas those of high molecular weight were, to some extent at least, deposited in the tissues. These observations are in accordance with those obtained by others who had fed the naturally occurring fatty acids. In addition to this it was observed that a conversion of saturated to unsaturated acids, and vice versa, also took place in the normal intact animal. Palmitic acid was reported as being transformed into homologues of higher and lower molecular weight, as well as into derivatives containing one double bond. Although a synthesis of oleic was clearly demonstrated, no indication that linoleic acid, Burr's essential fatty acid, could be formed *de novo* was achieved. Cetyl alcohol, a constituent of normal feces, was also found to be synthesized in vivo and was proved to arise from palmitic acid. When this alcohol was labeled with heavy hydrogen and fed to rats, deuteropalmitic acid, as well as deuterostearic acid, was isolated. This alcohol was thus assigned the role of an intermediate between these two acids, and it was suggested that other fatty acids might be formed similarly from other alcohols. While many transformations referred to above have been suggested by the work of others, Schoenheimer's data are probably the first clear-cut demonstration of their occurrence in the normal intact animal organism.

The phospholipids have not been overlooked by those interested in this new method of investigation. This phase of the question has been reviewed several times by Hevesy, his latest contribution appearing in the *Annual Review of Biochemistry* of 1940.¹¹ Chaikoff and his co-workers at the University of California have studied the phospholipid metabolism of different tissues of the white rat and have observed that a formation of new phospholipids takes place almost continuously in all the tissues investigated.^{12, 14} The activities of the tissues as far as this phospholipid turnover is concerned were ranked in the following order: liver and small intestine, very active; kidney, moderately active; stomach and large intestine, slightly active; and central nervous system, sluggish. In many respects these results are in accordance with the conceptions of Sinclair¹⁵ who employed elaidic acid as a tool for following lipid metabolism. Chaikoff¹³ has also demonstrated that the turnover in the liver is independent of the one taking place in the gastrointestinal tract, since it occurs even when that whole tract is removed. This emphasizes anew the importance of the liver in fat metabolism. These same workers have also observed that this turnover in the liver can be accelerated by the administration of choline¹⁶ and depressed by cholesterol.¹⁷ Such data offer an explanation of the fact that whereas fatty livers can be produced by feeding diets rich in cholesterol,¹⁵ the administration of choline¹⁹ prevents the accumulation of fat. Betaine has likewise been found to exert a lipotropic action,²⁰ and like choline it has been shown

to stimulate the turnover of phospholipids in the liver.²¹ In their most recent work the California investigators²² report that the amino acid methionine has a similar effect on the hepatic phospholipids. This was to be anticipated in the light of the demonstration²³ that this amino acid, like choline, prevents the formation of fatty livers of rats on low protein-high fat diets. In contrast to this, cystine, the other naturally occurring sulfur-containing amino acid, actually causes an increase in liver fat.²⁴ It was indeed surprising to find in this latest report by Chaikoff that cystine, like methionine, also stimulates the phospholipid turnover in the liver. This observation makes it difficult to explain the opposite effects on the total liver lipid contents that have been almost regularly observed when these acids were employed separately as supplements to low protein-high fat diets. It would be of interest to determine what influence Dragstedt's "lipocaine" would have upon this turnover. According to Dragstedt,²⁵ the action of lipocaine on fatty livers is different from that of choline, and if this is the case, perhaps some additional information can be obtained by the use of radioactive phosphorus. To date, Chaikoff and his co-workers have not fractionated the phospholipids, and it is impossible to state which of these were labilized as a result of the administration of choline and allied substances. In the light of the work of Chargaff,²⁶ however, it is probable that the lecithin fraction is the more labile one. Chaikoff and his aides²⁷ have determined the total phospholipid turnover of four different tumors transplanted into mice and report that the speed of this reaction resembles that of the more active tissues as the liver and kidney rather than that of the more stable muscles and brain.

In concluding this discussion it is fitting to call attention to the excellent work on the blood lipids that is being done in the Research Laboratory of the Children's Fund of Michigan. This group has not been content merely to determine the distribution of the lipids in the plasma and erythrocytes but has investigated the platelets and developed a method for the preparation of the stroma suitable for subsequent analysis.²⁸ Detailed studies, including total lipids, individual phospholipids, cholesterol, cholesterol esters, and neutral fat, have been made of the bloods of different species. A close relationship between size of cell and lipid content was shown to exist, the big avian cells containing large amounts of total lipids, the little sheep cells small amounts, with the human erythrocytes intermediate with regard to size and lipid content.²⁹ Almost all the lipids in the corpuscles of mammalia were found to be segregated in the stroma, indicating that these lipids are not concerned with the transport of fatty acids, but play a structural role in the makeup of the red blood cell.²⁹ Cephalin, which is not generally believed to be as intimately connected with lipid metabolism as is lecithin, was found to be the predominating lipid (45 per cent). The total lipid content, as well as the distribution of the individual phospholipids of the platelets, was found to be essentially like that of the stroma, the phospholipids comprising approximately 75 per cent and primarily in the form of cephalin.³⁰ This lipid has been assigned a role in the phenomenon of blood coagulation, and for this reason platelets obtained from a number of hemophiliacs were examined. Although a delay in disintegration time was clearly demonstrated, no deficiency in cephalin content was observed.³⁰ Thus the hemophiliac is abundantly supplied with cephalin; this raises the question as to

the delayed clotting time. Is the difference due perhaps to a variability of the constituent fatty acids in the cephalin molecules of the hemophiliacs? Unfortunately, micromethods applicable for determining the chemical nature of the fatty acids present in the small amounts of lipids obtainable from the platelets are as yet not available to answer this question. There is a definite need for such a procedure. Platelets obtained during menstruation, as well as those from one case of congenital thrombopenic purpura, were likewise found to be normal so far as lipid content and distribution are concerned.³¹

CLINICAL STUDIES OF THE ORGANIC ACID-SOLUBLE PHOSPHORUS OF RED BLOOD CELLS IN DIFFERENT ACIDOTIC STATES*

GEORGE M. GUEST, M.D., AND S. RAPOPORT, M.D., PH.D.
CINCINNATI, OHIO

EXCESSIVE phosphaturia in diabetes was noted and extensively studied around 1900 by von Noorden, Mandel and Lusk, and others.¹ In 1907 Fitz, Alsberg, and Henderson² found that hydrochloric acid given to rabbits by stomach tube led to greatly increased excretion of phosphates in the urine. These and other investigations of that period led to an understanding of the role of the urinary phosphates as buffer substances, and of the important mechanism by which the secretion of phosphates serves to conserve the base stores of the body in acidosis.³ For many years thereafter, however, little was learned concerning the physiologic adjustments which could permit or effect such changes in the urinary phosphate excretion.

In 1924 Haldane and his co-workers⁴ found that a reduced concentration of organic acid-soluble phosphorus in the blood cells was associated with large losses of phosphorus in the urine during ammonium chloride acidosis. They pointed out then that some of the bad effects of prolonged acidosis might be due to the depletion of the phosphorus reserves of the body. In 1927 Byrom⁵ found a great reduction in the concentration of the organic acid-soluble phosphorus (ester P) in the blood cells during severe diabetic acidosis. In 1937 Rapoport⁶ identified as diphosphoglyceeric acid the fraction of the organic acid-soluble phosphorus in the blood cells that decreased during ammonium chloride acidosis; and later the diphosphoglyceerate fraction in the blood cells was found to be similarly decreased in diabetic acidosis.⁷ Diphosphoglycerate in the blood appears, therefore, to be one source of the increased amount of phosphorus excreted in the urine in these two types of acidosis.

Contrasted with the phenomenon of increased phosphaturia in these types of acidosis, the excretion of phosphates in the urine was long known to be diminished in conditions with impaired renal function. In such conditions, an increase of inorganic phosphorus in the blood was accorded considerable diagnostic and prognostic importance as a sign of failure of renal function. Marriott and Howland⁸ in 1916 stressed the importance of the *retention* of inorganic phosphates as a factor in the production of nephritic acidosis. While the importance of this factor was debated by many investigators during the succeeding years, little attention was paid to the organic acid-soluble phosphorus compounds of the blood cells. In 1927 Byrom and Kay⁹ found an increased concentration of ester phosphorus in the blood cells of patients with severe nephritis, and in 1934 Ashley and Guest¹⁰ found similar changes in the blood cells of rabbits and

*From the Children's Hospital Research Foundation and the Department of Pediatrics, College of Medicine, University of Cincinnati.

dogs following the suppression of renal function by bilateral ureteral ligation, mercuric chloride poisoning, and diphtheria intoxication. Later, the increases of organic acid-soluble phosphorus in the blood cells under such conditions were accounted for in the diphosphoglycerate fraction.^{7, 11, 12}

Diphosphoglycerate normally makes up about half of the organic acid-soluble phosphorus of human blood. In a number of conditions, however, its concentration in the blood cells has been found to vary between wide limits: *increased*, after pyloric obstruction, following overdosage with irradiated ergosterol, and in nephrotis; *decreased*, in experimental rickets and in certain acidotic states. In such conditions, the changes in the blood cells probably reflect to a high degree the related and interdependent chemical changes which occur concomitantly in other body tissues. Thus, the concentrations of the acid-soluble phosphorus compounds in the blood, and the speed and direction of the reactions by which they are synthesized and decomposed, may constitute valuable indices of the state of the phosphorus stores and phosphorus metabolism of the whole body.

The data presented here demonstrate changes in the blood which have been found in acidotic states due to four different causes: the ingestion of ammonium chloride, diabetes mellitus, gastroenteritis in infants, and severe nephritis. The discussion that follows is designed to call attention to various factors which may influence such changes, and to emphasize their significance in the chemical pathology of these conditions.

METHODS

The methods used in these investigations are described elsewhere,^{7, 12} except for minor modifications.

In Tables I to IV, data on the phosphorus distribution in different types of blood are correlated with values, determined in the same samples, for the carbon dioxide content of serum, chloride concentrations in serum and cells, and serum pH. Chabanier and Lévy and co-workers¹³⁻¹⁶ have emphasized the value of the ratio between concentrations of chloride in cells and serum ($\text{Cl}_c:\text{Cl}_s$) as a measure of acidosis in clinical diagnosis. While this ratio is primarily dependent upon the pH of the blood, it appears to have additional importance in relation to changes of the organic acid-soluble phosphorus in the blood cells.

AMMONIUM CHLORIDE ACIDOSIS

Data in Table I illustrate changes found in the blood of one of us (S. R.) after the ingestion of 25 Gm. of ammonium chloride by mouth, in divided doses, on two successive days and 12 Gm. the third day. During three days of development of acidosis, the excretion of phosphorus in the urine was greatly increased, as has been observed repeatedly in this type of experiment by other investigators. Data in the two columns of Table I represent the findings on blood samples drawn before the experiment and at the end of the third day. In the latter sample, concentration of the blood is shown by the increased volume and number of red blood cells, and by the increased serum protein. The serum pH fell from 7.37 to 7.06. The carbon dioxide content of the blood decreased

more in the serum than in the cells; and the concentration of chloride increased more in the cells than in the serum. The inorganic phosphorus in the whole blood decreased slightly. The concentration of organic acid-soluble phosphorus in the cells decreased markedly, and this decrease was practically all accounted for by a nearly equal decrease in the diphosphoglycerate.

This experiment has been reported elsewhere, with a chart illustrating intermediate changes found in blood samples drawn during the development of acidosis and during recovery.*

TABLE I

AMMONIUM CHLORIDE ACIDOSIS

DATA ON THE BLOOD OF S. R., BEFORE AND AFTER TAKING 62 GM. OF AMMONIUM CHLORIDE BY MOUTH IN DIVIDED DOSES DURING THREE SUCCESSIVE DAYS

	BEFORE	AFTER
Volume of cells in whole blood (%)	42.9	50.6
Red cell count (millions per c. mm.)	4.99	5.87
Hb in whole blood (Gm. per 100 c.c.)	14.7	18.0
Protein, serum (Gm. per 100 c.c.)	6.6	8.9
pH of serum	7.37	7.06
CO ₂ content, serum (meq. per 1)	28.2	15.8
CO ₂ content, cells (meq. per 1)	18.8	15.3
Cl, serum (meq. per 1)	103.0	109.2
Cl, cells (meq. per 1)	50.6	66.9
Ratio Cl _s :Cl _c	0.49	0.61
Phosphorus (mg. per 100 c.c.)		
Inorganic P, serum	4.2	3.5
Organic acid-soluble P, cells	47.9	32.5
Diphosphoglycerate P, cells	28.4	16.0

Diphosphoglycerate P, cells	< 3.0	36.4	7.1	29.3

DIABETIC ACIDOSIS

Examples of data on blood samples drawn from two patients in diabetic coma, and after recovery, are presented in Table II. These patients were adults, on the medical service of the Cincinnati General Hospital. Both had been in coma several hours before they were brought to the hospital, when the first blood samples were drawn. The first patient, E. W., is the subject of a chart

*Chart 5.

in another paper,* a chart which shows graphically the progressive changes which were found in the blood samples drawn from this patient at intervals during the recovery period. From a series of similar patients thus far studied, these two are selected for presentation here because of striking differences in concentration of chloride in the blood serum in the two initial blood samples.

In the first samples of blood drawn from both patients, a severe degree of acidosis was indicated by the extraordinarily low values for pH and carbon dioxide content of the serum, and with these changes the concentration of organic acid-soluble phosphorus and diphosphoglycerate in the cells was very low. While the concentration of chloride in the serum was relatively high in the serum of one (E. W.), and low in the serum of the other (P. H.), the concentration of chloride in the cells of both was increased, and the ratios $\text{Cl}_c:\text{Cl}_s$ were very high. The high inorganic phosphorus in the first sample of blood of P. H. can be ascribed to severe dehydration and beginning failure of renal function. After recovery all values returned to within normal limits. The recovery of a normal chemical structure of the blood varies in individual cases, however, and does not necessarily parallel symptomatic recovery.

TABLE III
ACIDOSIS DUE TO GASTROENTERITIS IN THREE INFANTS

	D. C. (AGE, 1 MO.)	J. B. (AGE, 2 MO.)	W. S. (AGE, 7 MO.)
Volume of cells in whole blood (%)	44.1	35.0	48.5
Red cell count (millions per c. mm.)	4.29	3.30	6.2
Hb in whole blood (Gm. per 100 c.c.)	14.8	10.0	16.3
Urea N (mg. per 100 c.c.)			73.0
CO_2 content, serum (meq. per 1)	5.3	4.9	10.8
Cl, serum (meq. per 1)	114.0	119.0	114.0
Cl, cells (meq. per 1)	101.1	90.7	
Ratio $\text{Cl}_c:\text{Cl}_s$	0.89	0.76	
Phosphorus (mg. per 100 c.c.)			
Inorganic P, whole blood	6.3	7.8	2.8
Organic acid-soluble P, cells	30.8	28.2	25.5

ACIDOSIS OF GASTROENTERITIS IN INFANTS

In Table III are listed data on blood samples from three infants, 1, 2, and 7 months of age, respectively, suffering from acute profuse diarrhea, dehydration, and severe acidosis. In a series of cases of gastroenteritis thus far studied, the blood changes illustrated here are typical of the state of acidosis that develops in infants when severe diarrhea is attended by little or no vomiting. Other types of change are found, however, when excessive vomiting, renal impairment, and other factors play variable roles in the disturbance; these will be treated more fully in later communications.

In each case the carbon dioxide content of the serum and the concentration of organic acid-soluble phosphorus in the cells was very low. The concentration of chloride was increased in both serum and cells, and the ratio $\text{Cl}_c:\text{Cl}_s$ was very high, indicating a very low pH. More complete analyses were not made because of the limitations imposed by the small blood samples available.

*Chart 7.

Other investigators have demonstrated, however, that the state of acidosis in this type of disturbance is characterized by a low concentration of total base in the blood serum, i.e., a base deficit due to losses of base in diarrheal stools.^{17,18}

TABLE IV

NEPHRITIS

EXAMPLES OF DATA ON BLOOD SAMPLES FROM PATIENTS WITH VARYING DEGREES OF RENAL IMPAIRMENT AND IN DIFFERENT CONDITIONS OF ACIDOSIS

NEPHRITIS

Data in Table IV permit comparisons of different patterns of blood changes found in four patients suffering with severe impairment of renal function of varying duration and severity. The data indicating anemia, low carbon dioxide content, and high concentrations of nonprotein nitrogen and of inorganic phosphorus in the blood are characteristic of nephritic acidosis. However, the concentrations of organic acid-soluble phosphorus in the cells, and of chloride in the serum and cells, differed widely among the four blood samples represented here. A tentative interpretation of the significance of these findings is offered in the discussion that follows.

1. *Subacute bacterial endocarditis, hemorrhagic nephritis.* E. S., white female, 15 years of age. Her illness of eight months' duration began with signs of rheumatic heart disease and progressed slowly, with increasing signs of cardiac decompensation, slight edema, hematuria, occasional vomiting, etc. Death occurred with convulsions one week after this blood sample was taken.

2. *Chronic glomerulonephritis.* C. P., colored male, 9 years of age. The duration of illness is uncertain. The boy was first admitted to the hospital two years previously, with acute nephritis associated with edema, albuminuria, elevated blood pressure, and urea clearance of only around 3 per cent. During two years he was readmitted to the hospital several times with exacerbations of the same symptoms. He died two days after this blood sample was taken.

3. *Renal rickets.* P. G., white male, 9 years of age. A diagnosis of congenital malformation of the bladder, hydronephrosis, and renal rickets was made when this boy, at the age of 5 years, was first brought to the hospital because of poor development and poor weight gain, occasional vomiting, and urinary incontinence. His renal function measured less than 10 per cent of phenolsulfonephthalein excretion in two hours. At the time this blood sample was taken, he had been brought to the hospital after five days of increasing illness, apparently precipitated by a mild respiratory infection. He was then very drowsy, breathing

was labored, and the blood showed an extreme acidosis. Following the administration of sodium bicarbonate to correct this acidosis, he showed a remarkable transient improvement of his symptoms, but he died a month later.

4. *Nephrosclerosis*. R. H., white male, 13 years of age. The duration of illness is uncertain. There was a history of increasing weakness, anemia, muscle cramps, etc., since less than 2 years; pus and albumin in the urine were noted by physicians during the same period. The mother reported having seen "strings of pus" in the urine since infancy. He had convulsions during a respiratory infection when 2 years old, but apparently had none during an attack of scarlet fever at 6 years of age. During nearly a year's observation in this hospital he has had several exacerbations of acute symptoms, with vomiting, marked anemia, variable azotemia, and with Trousseau and Chvostek signs occasionally positive. This blood sample was taken at a time when he was feeling comparatively well, although it was deemed necessary to give him a transfusion shortly afterward because of the low red blood cell count and hemoglobin found in this sample.

DISCUSSION

Several recognized functions of the organic acid-soluble phosphorus compounds of the blood cells have been discussed previously in a series of papers based on experimental and clinical studies carried on in this laboratory. These substances participate in carbohydrate metabolism, serve in the transport of phosphorus in the body for various metabolic needs, and play an important role in the maintenance of the acid-base equilibrium of the blood.

In earlier papers of this series attention was called to a reciprocal relationship that was observed between changes in concentration of organic acid-soluble phosphorus and chloride in the blood cells following pyloric obstruction¹⁹ and after suppression of renal function.¹⁰ More recently available data on the several fractions of the organic acid-soluble phosphorus have permitted a fairly complete description of the ionic composition of blood cells, both in the normal state and in several conditions in which severe disturbances of the blood electrolytes are known to occur. When the organic phosphorus compounds are taken into consideration, close agreement is obtained between the total base and the sum of the anions in the cells. Evidence has been presented that the distribution of the diffusible ions, H^+ , Cl^- , and HCO_3^- , between cells and serum depends mainly upon the concentration and anion equivalency of diphosphoglyceric acid and hemoglobin, the two most important nondiffusible constituents of the cells.^{12, 20}

Changes in concentration of the organic acid-soluble phosphorus compounds in the blood cells appear to be subject to several interdependent factors: the functional state of the tissue phosphorus reserves, the excretion of phosphates by the kidneys, the changes in concentration of other electrolytes in the blood; and also, various factors affecting the reactions of the glycolytic cycle by which these phosphoric esters are synthesized and decomposed. Among the latter, an important factor is the pH of the blood which is especially to be considered in the states of acidosis discussed in the present paper. In blood incubated in vitro, acidification to pH 7.0 to 7.3 leads to a rapid liberation of inorganic phosphorus at the expense of diphosphoglycerate, while reactions above pH 7.3 favor the esterification of inorganic phosphorus and synthesis of diphosphoglycerate.²¹ The fact that decomposition of diphosphoglycerate is favored by a range of reactions seen frequently in the blood in vivo offers an explanation

of one mechanism by which its concentration in the blood cells is reduced in states of acidosis such as those cited in Tables I, II, and III. Closely related to the effect of pH is the distribution of chloride between cells and serum. Observations of reciprocal relationships between changes in concentrations of chloride and diphosphoglycerate in the blood cells in a variety of conditions suggest that the concentration of chloride in itself may exert an influence on the synthesis and decomposition of diphosphoglycerate.

Other phosphorus stores of the body are, however, more important than the diphosphoglycerate of the blood as a source of the increased urinary phosphorus in acidosis. The fact that during the development of acidosis the increased phosphaturia at first is not accompanied by much, if any, increase in calcium excretion indicates that the phosphorus of soft tissues is liberated before that of bone. Phosphorus compounds of the soft tissues are closely related to those of the blood, and apparently are similarly affected by acidotic conditions. A rapidly developing severe acidosis may lead to exhaustion of the labile phosphorus reserves before the large phosphorus stores in bone can be mobilized. This loss in turn may lead to a series of interrelated disturbances. Since phosphorus is known to play an essential role in respiration and in carbohydrate metabolism, exhaustion of the labile phosphorus reserves can be expected to affect adversely the metabolic activity of various tissues. Added to this is the fact that the excretion of phosphates and other acid metabolites entails a loss of base which, if continued beyond a relatively short time, results in a lowered concentration of total base in the blood and tissues. The base deficit thus produced is a well-recognized factor in the dehydration of acidosis, and both base deficit and dehydration may aggravate the state of acidosis. Thus, acidosis from any cause is likely to create a vicious cycle in which different changes mutually intensify the severity of each other.

Such a vicious cycle can be visualized readily in the development of acidosis with gastroenteritis in infants. Losses of base in diarrheal stools result in base deficits in the blood and tissues, acidosis, and dehydration. Acidosis favors the decomposition of the labile organic acid-soluble phosphorus compounds of the blood and tissues, giving rise to increased phosphaturia; with this, losses of base in the urine augment those already occurring in the stools. The decomposition of diphosphoglycerate proceeds simultaneously with increases in concentration of chloride in the blood cells, shifts in distribution of chloride between serum and cells, and changes of pH, so that each set of changes can be said to influence the other.

Failure of excretion of phosphates in the urine, due to acute suppression of renal function, is followed by changes of the organic acid-soluble phosphorus and chloride in the blood cells in directions opposite to those described as occurring in chloride and diabetic acidosis in subjects with adequate renal function. Some of the effects of abrupt cessation of renal function have been illustrated in another paper in a chart representing blood changes in a dog after bilateral nephrectomy.^{7*} Briefly, those changes were progressive increase of nonprotein nitrogen and inorganic phosphorus in the blood; increase of organic acid-soluble phosphorus in the cells, accounted for by equal increases in the diphospho-

*Chart 3.

glycerate fraction; decrease of HCO_3 and Cl in both serum and cells. Such changes are typical of those found in the blood of many nephritic patients suffering from acute suppression of urinary excretion. However, not all cases commonly called "nephritic acidosis" show blood changes falling into this pattern.

The values listed in columns 1 and 2 of Table IV are, in fact, very much like those found at different times after nephrectomy in the experiment just described. In these two bloods, *high* concentrations of organic acid-soluble phosphorus in the cells accompanied low concentrations of carbon dioxide in the serum, and in the second, the chloride was low in both serum and cells. In column 3, however, is shown a picture fairly similar to those of other types of acidosis previously discussed, i.e., *low* concentration of organic acid-soluble phosphorus in the cells, with low carbon dioxide content of the serum and a high $\text{Cl}_c:\text{Cl}_s$ ratio. In column 4 a *normal* concentration of organic acid-soluble phosphorus accompanies decreased values for both carbon dioxide and pH in the serum, and a high $\text{Cl}_c:\text{Cl}_s$ ratio. These values probably resulted from a balance between the effects of acidosis and of phosphate retention, respectively favoring decreases and increases of organic acid-soluble phosphorus in the cells. Differences between the response to acidosis in these two patients, represented in columns 4 and 5, may have been due to slight differences in their ability to get rid of endogenous phosphates, and possibly also to differences in their phosphorus reserves, exhausted more or less during a long period of borderline acidosis. In terminal stages, "uremia" is characterized by great increases of organic acid-soluble phosphorus in the cells, with extreme acidosis; under such conditions the inorganic phosphorus is always very high. Presumably the increase of diphosphoglycerate in the cells under such conditions is due to the retention of phosphates, but the mechanism by which this increase occurs, together with concomitant shifts in other electrolytes, is by no means clear.

SUMMARY

The concentration of organic acid-soluble phosphorus in the blood cells is greatly reduced during severe acidosis in subjects with adequate renal function, following the ingestion of ammonium chloride, in diabetic coma, and in infants with profuse diarrhea. The decrease is in the diphosphoglycerate fraction, which appears to be one source of the increased phosphaturia that occurs in these conditions. High, normal, or low concentrations of organic acid-soluble phosphorus in the blood cells may be found during acidosis in nephritic subjects with low renal function, depending upon different conditions present in individual cases. The changes of phosphorus distribution are closely related to the state of other electrolytes in the blood, and they appear to constitute a valuable index of the functional state of the labile phosphorus reserves of the body.

SOME CHEMICAL OBSERVATIONS ON THE HUMAN HEART IN HEALTH AND DISEASE*

VICTOR C. MYERS, PH.D., D.SC., AND GEORGE H. MANGUN, PH.D.
CLEVELAND, OHIO

DURING recent years the problem of myocardial failure has been attacked vigorously from many directions. Not least among these has been the chemical approach to the problem. As the new concept of the chemical nature of the mechanism of muscle contraction has been elaborated, new possibilities have arisen which, although at the present time in an embryonic state of development, may ultimately prove to be of great practical importance in clinical medicine.

It is not intended here to attempt to give a review of the entire field of the chemistry of the heart and of heart failure. Numerous reviews have appeared upon the subject, particularly those concerned with the gaseous metabolism of the heart and carbohydrate metabolism. Bodansky and Bodansky³ have recently summarized the chemical blood changes associated with cardiac insufficiency. The present communication will deal largely with a discussion of the chemical composition of the heart muscle itself and some of the factors that have been found to influence it.

NORMAL COMPOSITION

Heart muscle may be divided into an intracellular and extracellular phase, similar to that which has received much attention in skeletal muscle. It differs from skeletal muscle in that there is relatively more extracellular and less intracellular phase. Hastings, Blumgart, Lowry, and Gilligan¹⁵ have determined the normal phase relationships in the dog heart. They found that the water content of the intracellular phase paralleled that of other tissues which Hastings and his collaborators studied. The water content of the whole tissue is higher than that of skeletal muscle, but the extra water is associated with sodium and chloride and, therefore, assumed to be extracellular. In young dogs it was found that there was more extracellular fluid than in adult dogs. Samples from the left ventricle, right ventricle, and septum showed that the intracellular phase was the greatest in the left ventricle and least in the right ventricle.

In the human heart the intracellular phase is likewise smaller than in skeletal muscle. This is reflected in the lower concentration of potassium and the higher chloride and sodium content of the hearts examined after death by the Vanderbilt investigators,²⁰ and by other workers.²² The right ventricle of man contains considerably more extracellular phase than that of the dog,

causing an apparent wide difference in the concentrations of potassium, creatine, phosphorus, and other substances between the two ventricles. However, there is no chemical evidence to indicate that this is due in any part to factors other than differences in the extracellular water, connective tissue, and fat content, all of which are greater in the right ventricle. We have found that the intracellular constituents, creatine, phosphorus, and potassium, are approximately equal in both ventricles when corrected to a constant water content in the collagen and fat-free tissue (unpublished observations).

CREATINE AND PHOSPHORUS COMPOUNDS

Since the discovery of phosphocreatine by Fiske and Subbarow¹³ in 1927, a number of investigators have directed special attention toward its role in the heart. Inasmuch as phosphocreatine cannot be determined in the human heart at autopsy, due to its extreme lability, studies upon its variations have been carried out either on animals experimentally or on the human heart by observing the creatine content. Creatine has proved to be a particularly easy substance to study, because, of all the compounds so far investigated, it has shown the greatest and probably the most significant variations. Due to its close association as phosphocreatine with the final steps in the transfer of energy from the chemical system to mechanical energy, and the ease with which it may be determined, it has lent itself to the study of many problems as an index of the net effect of any disease or experimental procedure upon the heart muscle.

Creatine is present in heart muscle in about half the concentration it attains in skeletal muscle. Phosphocreatine has been reported by various investigators as present in concentrations from one-tenth to one-third that of skeletal muscle. Its lower concentration in heart muscle than in skeletal muscle cannot be attributed to a difference in the amount of the intracellular phase, since there is a sharp decrease in the ratio of creatine to potassium. The distribution of phosphorus compounds is likewise greatly different from that of skeletal muscle. While the total phosphorus of the heart is about the same as that of skeletal muscle, a much greater part is present in the acid-insoluble fraction, most of which is phospholipid. The acid-soluble fraction is accordingly less, and this difference may be traced largely to the lower phosphocreatine content of the heart.

The chemical composition of the normal and failing human heart is shown in Table I. Where normal data were not available, average values for miscellaneous autopsy cases are given.

While the full implications of muscle creatine were not recognized until the discovery of phosphocreatine in 1927, and its subsequent correlation with muscle contraction, creatine has long been regarded as closely associated with muscle contraction.¹⁸ It is interesting to note that the chemical approach in the human myocardium to the problem of heart failure was first attacked through this compound and that to date no other substance has been conclusively shown to be as greatly affected by myocardial insufficiency. While much evidence has accumulated indicating that the loss of creatine is due to failure of the chemical system supplying energy for the resynthesis of phosphocreatine, creatine nevertheless remains as the outstanding substance by which the degree

of deficiency of the chemical mechanism may be evaluated in the human heart. This situation arises as a result of the close association of creatine with the final step in the transfer of energy to the mechanical phase of contraction and its stability and ease of measurement. Phosphocreatine and adenylypyrophosphate which are even more closely linked with contraction cannot be evaluated in the human heart because of their extreme lability.

Studies on the creatine content of the human heart began with the work of Constabel.⁷ In essentially normal persons he found values of 170 to 180 mg. Lower values were reported in persons whose heart action was poor, particularly where fatty changes in the myocardium were evident.

The greater part of the investigations on the human heart were undertaken after the discovery of phosphocreatine. For the sake of clarity, they will be discussed from the standpoint of interpretations placed upon them rather than chronologic order.

Normal Values.—The values reported by Constabel⁷ appear to be low in the light of more recent data. Vollmer²⁸ reported averages of 221 mg. and 173 mg.

of creatine for the left and right ventricles, respectively. In three normal persons, Bodansky² obtained values ranging from 220 mg. to 285 mg., presumably in the left ventricle. In 48 human hearts, which he considered to be normal, Cowan reported values ranging from 117 mg. to 264 mg., with an average of 194 mg. In 95 miscellaneous cases obtained within thirty-six hours post mortem, Linegar, Frost, and Myers²⁰ obtained an average of 208 mg. and 149 mg. for the left and right ventricles, respectively. Herrmann, Decherd, and Oliver²¹ reported an average of 175 mg. in 34 hearts which they considered to be essentially normal. In another series of miscellaneous cases, Mangun, Reichle, and Myers²² found average values of 199 mg. and 148 mg. in the left and right ventricles, respectively. Bodansky, Pileher, and Duff⁴ studied 212 males and 88 females and reported average values of 157 mg. and 163 mg., respectively, in the left ventricles of the two sexes.

To gain more accurate information about the normal creatine content of the human heart, Mangun and Myers²² obtained samples from a limited number of persons whose death was sudden. In 13 cases the creatine content of the left ventricle varied from 186 mg. to 218 mg., and averaged 203 mg., and the right ventricle varied from 154 mg. to 185 mg., and averaged 165 mg. These values were far more constant than the values found in any of our pathologic studies and indicate that the normal creatine content of the myocardium is fairly uniform, in contrast to variations of large magnitude in both directions in diseased persons.

EFFECT OF AGE, SEX, GENERAL CONDITION

Constabel⁷ was able to find no correlation between the creatine content of the myocardium and age and sex. Later studies, however, indicate that some correlation does exist. Seebof, Linegar, and Myers²¹ found that the creatine content of the newborn infants was approximately the same in both ventricles. The creatine content of both ventricles was found to rise rapidly and reach a maximum within the first year, after which there was no change up to the age of 30. Between the ages of 30 and 50 there appeared to be a slight drop, after which the values again increased. However, it is difficult to demonstrate any positive correlation during the later years because of the relatively small variations and the possibility of the incidence of disease at different age levels affecting the results. Bodansky, Pileher, and Duff⁴ recorded a slightly higher cardiac creatine content in women than in men.

A comparison of our normal group with miscellaneous pathologic cases indicates that the heart tends to maintain a high creatine level in the absence of severe cardiac involvement. Only rarely are values below 170 mg. encountered in the left ventricle in the absence of myocardial insufficiency or degenerative changes in the myocardium. We have encountered numerous cases in which the creatine content of the pectoralis major was sharply decreased without appreciable decrease in the myocardium. Occasionally the creatine content of the heart is low in acute infections, possibly due to a direct action of the bacteria or their toxic products on the myocardium. In chronic conditions, such as carcinoma and diabetes, cardiac creatine values tend to be slightly lower than normal, but seldom fall in the range encompassing most cases of myocardial

insufficiency. Because of the overlapping of pathologic conditions, it is difficult to convey the true status of individual cases in tabular form without accompanying diagnoses.

We have encountered numerous cases in our studies in which the myoeardial creatine values are elevated markedly without apparent cause. . Particularly prominent in this group are cases with histories of fever. Daus and Myers (unpublished data) have recently studied the effect of experimental hyperthermia on the creatine content of rat skeletal muscle. They found the creatine content increased, partly due to dehydration and partly due to an increased creatine content per unit of dry tissue. Whether this increase is due to a loss of muscle solids without a parallel loss of creatine, or whether there was an increased rate of formation could not be determined from the data obtained.

In uremia Linegar, Frost, and Myers²⁰ found a definite elevation of creatine in both heart and skeletal muscles. By the retention of creatinine, the creatine-creatinine equilibrium would be shifted toward the former. It is interesting to note that Mangun, Reichle, and Myers,²³ have also observed a tendency toward elevation of phosphorus and potassium, suggesting the possibility that the extra creatine may be retained as the potassium salt of creatine phosphoric acid. Whether this might exert a beneficial effect on the heart by increasing the energy and base reserve of the myocardium is an interesting speculation.

MYOCARDIAL INSUFFICIENCY

Since the first investigation of creatine in the human heart by Constabel,⁷ it has become more and more apparent that this substance is decreased in the failing heart. On this point, all investigators in this field are agreed. The work of Vollmer,²⁸ Cowan,⁸ Linegar, Frost, and Myers,²⁰ Bodansky and Pilcher,⁴ Herrmann and his associates,^{16, 17} and Mangun, Reichle and Myers,²³ have clearly demonstrated that a loss of creatine is usually associated with myocardial decompensation. The underlying cause of the decrease in creatine content of the myocardium, however, has often been challenged. It has been suggested at various times that the decrease in creatine was due to anatomic changes in the muscle, to edema, to injury of the cell membranes, permitting its diffusion out of the cells, and to hypertrophy of noncreatine containing parts of the cell. The final alternative is that the loss of creatine is due to chemical events within the cell, an inability to maintain the creatine in the nondiffusible form of phosphocreatine.

Let us examine more closely the changes that take place in the failing heart. Determinations of the water content by various investigators have demonstrated that only a small fraction of the drop in creatine content can be assigned to this factor.⁹ While there is usually a small increase in the water content of the failing heart, and occasionally a significant increase,^{24, 29} this factor is negligible with respect to creatine, although it may be of importance in itself as a factor interfering with the metabolic activity of the myocardium. The possibility that anatomic alterations, such as fatty infiltration and increases in connective tissue, may be responsible have been discounted by workers who have examined the heart histologically in conjunction with their analyses.^{8, 16} In our series of studies we have determined the water, fat, and collagen content in a limited num-

of creatine for the left and right ventricles, respectively. In three normal persons, Bodansky² obtained values ranging from 220 mg. to 285 mg., presumably in the left ventricle. In 48 human hearts, which he considered to be normal, Cowan reported values ranging from 117 mg. to 264 mg., with an average of 194 mg. In 95 miscellaneous cases obtained within thirty-six hours post mortem, Linegar, Frost, and Myers²⁰ obtained an average of 208 mg. and 149 mg. for the left and right ventricles, respectively. Herrmann, Decherd, and Oliver²¹ reported an average of 175 mg. in 34 hearts which they considered to be essentially normal. In another series of miscellaneous cases, Mangun, Reichle, and Myers²³ found average values of 199 mg. and 148 mg. in the left and right ventricles, respectively. Bodansky, Pileher, and Duff⁴ studied 212 males and 88 females and reported average values of 157 mg. and 163 mg., respectively, in the left ventricles of the two sexes.

To gain more accurate information about the normal creatine content of the human heart, Mangun and Myers²² obtained samples from a limited number of persons whose death was sudden. In 13 cases the creatine content of the left ventricle varied from 186 mg. to 218 mg., and averaged 203 mg., and the right ventricle varied from 154 mg. to 185 mg., and averaged 165 mg. These values were far more constant than the values found in any of our pathologic studies and indicate that the normal creatine content of the myocardium is fairly uniform, in contrast to variations of large magnitude in both directions in diseased persons.

EFFECT OF AGE, SEX, GENERAL CONDITION

Constabel⁷ was able to find no correlation between the creatine content of the myocardium and age and sex. Later studies, however, indicate that some correlation does exist. Seebof, Linegar, and Myers²⁷ found that the creatine content of the newborn infants was approximately the same in both ventricles. The creatine content of both ventricles was found to rise rapidly and reach a maximum within the first year, after which there was no change up to the age of 30. Between the ages of 30 and 50 there appeared to be a slight drop, after which the values again increased. However, it is difficult to demonstrate any positive correlation during the later years because of the relatively small variations and the possibility of the incidence of disease at different age levels affecting the results. Bodansky, Pileher, and Duff⁴ recorded a slightly higher cardiac creatine content in women than in men.

A comparison of our normal group with miscellaneous pathologic cases indicates that the heart tends to maintain a high creatine level in the absence of severe cardiac involvement. Only rarely are values below 170 mg. encountered in the left ventricle in the absence of myocardial insufficiency or degenerative changes in the myocardium. We have encountered numerous cases in which the creatine content of the pectoralis major was sharply decreased without appreciable decrease in the myocardium. Occasionally the creatine content of the heart is low in acute infections, possibly due to a direct action of the bacteria or their toxic products on the myocardium. In chronic conditions, such as carcinoma and diabetes, cardiac creatine values tend to be slightly lower than normal, but seldom fall in the range encompassing most cases of myocardial

insufficiency. Because of the overlapping of pathologic conditions, it is difficult to convey the true status of individual cases in tabular form without accompanying diagnoses.

We have encountered numerous cases in our studies in which the myoeardial creatine values are elevated markedly without apparent cause. Particularly prominent in this group are cases with histories of fever. Daus and Myers (unpublished data) have recently studied the effect of experimental hyperthermia on the creatine content of rat skeletal muscle. They found the creatine content increased, partly due to dehydration and partly due to an increased creatine content per unit of dry tissue. Whether this increase is due to a loss of muscle solids without a parallel loss of creatine, or whether there was an increased rate of formation could not be determined from the data obtained.

In uremia Linegar, Frost, and Myers²⁰ found a definite elevation of creatine in both heart and skeletal muscles. By the retention of creatinine, the creatine-creatinine equilibrium would be shifted toward the former. It is interesting to note that Mangun, Reiehle, and Myers,²³ have also observed a tendency toward elevation of phosphorus and potassium, suggesting the possibility that the extra creatine may be retained as the potassium salt of creatine phosphoric acid. Whether this might exert a beneficial effect on the heart by increasing the energy and base reserve of the myocardium is an interesting speculation.

MYOCARDIAL INSUFFICIENCY

Since the first investigation of creatine in the human heart by Constabel,⁷ it has become more and more apparent that this substance is decreased in the failing heart. On this point, all investigators in this field are agreed. The work of Vollmer,²⁸ Cowan,⁸ Linegar, Frost, and Myers,²⁰ Bodansky and Pileher,⁴ Herrmann and his associates,^{16, 17} and Mangun, Reiehle and Myers,²³ have clearly demonstrated that a loss of creatine is usually associated with myoeardial decompensation. The underlying cause of the decrease in creatine content of the myocardium, however, has often been challenged. It has been suggested at various times that the decrease in creatine was due to anatomic changes in the muscle, to edema, to injury of the cell membranes, permitting its diffusion out of the cells, and to hypertrophy of noncreatine containing parts of the cell. The final alternative is that the loss of creatine is due to chemical events within the cell, an inability to maintain the creatine in the nondiffusible form of phosphocreatine.

Let us examine more closely the changes that take place in the failing heart. Determinations of the water content by various investigators have demonstrated that only a small fraction of the drop in creatine content can be assigned to this factor.⁹ While there is usually a small increase in the water content of the failing heart, and occasionally a significant increase,^{14, 29} this factor is negligible with respect to creatine, although it may be of importance in itself as a factor interfering with the metabolic activity of the myocardium. The possibility that anatomic alterations, such as fatty infiltration and increases in connective tissue, may be responsible have been discounted by workers who have examined the heart histologically in conjunction with their analyses.^{8, 10} In our series of studies we have determined the water, fat, and collagen content in a limited num-

ber of cases and have been unable to demonstrate any serious alterations in the values for creatine, phosphorus, and potassium after correction for these factors. Occasionally in a heart the fat and collagen content, particularly of the right ventricle, have been found to be increased, but these alterations in individual cases exerted a negligible effect upon the group of cases studied in this manner. It would, nevertheless, be highly desirable to have more extensive studies conducted upon the collagen content of the heart, especially in relation to age, hypertrophy, and infarction.

The possibility that injury of the cell membrane is responsible for the loss in creatine seems hardly credible. There is ample evidence in the literature to indicate that creatine may be taken up by muscle as well as released by it. The more plausible explanation, then, would be that the creatine saturation level of the myocardium is decreased as a result of a decrease in phosphocreatine.

The studies of the Vanderbilt investigators²⁰ demonstrated that there is a loss of potassium and phosphorus from the heart in congestive heart failure. However, there appears to be some conflict of opinion as to the possible role of potassium as a contributory cause in heart failure. Herrmann and his co-workers¹⁶ concluded that the slight losses of potassium which they observed were not significant. It is true that the per cent loss of potassium from the failing heart is considerably less than that of creatine and more variable. The decrease of phosphorus in the failing heart has been confirmed by Mangun, Reichle and Myers²³ and by Decherd and Blum.¹¹ The latter authors demonstrated that the phosphorus loss was confined mostly to the acid-soluble fraction, an observation in full accord with some of our unpublished studies.

Work carried out in this laboratory led us to believe that a close correlation existed between the losses of creatine, phosphorus, and potassium. In analyzing data obtained on a series of autopsy cases, it soon became apparent that the loss of creatine was far greater on a percentage basis than that of either potassium or phosphorus. However, in further studying the results, Mangun, Reichle and Myers²³ noted that the loss in millimoles was more than twice as large for both potassium and phosphorus as for creatine. It was accordingly concluded that the observed changes were due to a loss of the dipotassium salt of creatine phosphoric acid, together with other acid-soluble phosphorus compounds.

In 1937 Burns and Cruickshank⁵ published a very interesting paper in which they studied the effects of asphyxia and fatigue on the excised heart of the cat. They found that when the heart was arrested in certain stages of asphyxia a loss of phosphagen (phosphocreatine) preceded that of adenylypyrophosphate, with a loss of about 80 and 60 per cent of phosphagen and adenylypyrophosphate, respectively, with complete asphyxiation. Similar results were obtained with the heart of the dog. In the presence of oxygen, however, fatigue produced only a slight loss of phosphagen, with a relatively greater loss of adenylypyrophosphate, about a 25 and 50 per cent loss of phosphagen and adenylypyrophosphate, respectively.

To determine more accurately what changes took place in the creatine and phosphorus compounds of the heart in insufficiency, Mangun and Roberts²²

studied the distribution of phosphorus compounds in the left ventricle of the dog's heart in late aortic insufficiency. No decrease in either phosphocreatine or adenylypyrophosphate was observed in dogs with varying degrees of hypertrophy without decompensation. However, in two dogs in the very late stages of aortic insufficiency with decompensation, it was found that there was a decrease in creatine, total acid-soluble phosphorus, phosphocreatine, and adenylypyrophosphate. The most striking change in the hearts of these dogs was the marked loss of adenylypyrophosphate, which was decreased about 40 per cent in both animals. The loss of phosphocreatine was less apparent, being slightly lower than the lowest normal value in a series of 8 normal animals and about 15 per cent below the average normal value. The loss of acid-soluble phosphorus was completely accounted for by the decreases in adenylypyrophosphate and phosphocreatine. The loss of creatine was about half accounted for by the decrease in phosphocreatine.

The findings in the animal experiments of Mangun and Roberts²⁴ have essentially fitted into our concept of the chemical nature of heart failure. In addition, their findings paralleled those of Burns and Cruickshank⁵ on isolated animal hearts fatigued in the presence of oxygen rather than their experiments on asphyxial arrest. The observations are too few to permit the drawing of definite conclusions as to the relative roles of fatigue and anoxemia in decompensation, but indicate that the former may be the predominant factor.

The strategic position occupied by adenylypyrophosphate with respect to phosphocreatine, glycolysis, energy transfer, and phosphorus transfer seemed to warrant further investigations. Since it is impossible to determine the concentration of adenylypyrophosphate in the human heart due to its rapid breakdown to adenylic acid and subsequent deamination, we attempted to determine it by measuring the oxypurine nitrogen content. This we did by treating a trichloroacetic acid extract of heart muscle with nitrous acid in a boiling water bath and subsequently determining the purine bases by the method of Hitchings (1933). A preliminary report of nine cases was given before the 1940 meeting of the American Society of Biological Chemists. Since that time a total of 24 cases have been studied. In 6 cases of myocardial insufficiency the average oxypurine content of the left ventricle was about 15 per cent lower than the average of the remaining 18 cases in the series. Only one of the 6 cases showed a relatively high oxypurine content; this was a case of acute rheumatic fever of short duration following childbirth. Total acid-soluble phosphorus and creatine determinations were also made on this series. In general, these substances varied in the same direction as the purine content. In the group with insufficiency the total acid-soluble phosphorus was about 15 per cent below that of the other cases and the creatine was about 33 per cent lower.

CARDIAC HYPERTROPHY

The question of the effect of cardiac hypertrophy upon the chemical composition of the human heart is of importance both as a phenomenon in itself and in relation to myocardial failure. Herrmann and his co-workers^{16, 17} and others look upon hypertrophy as intimately associated with failure, possibly the principal factor in bringing about an eventual inability of the metabolic trans-

fer between the blood and muscle to keep pace with the increased demands upon the energy output. Roberts, Wearn, and Badal²⁶ have shown that as a result of the increase in diameter of the muscle fibers there is a decrease in the number of capillaries per square millimeter of heart muscle. This leads to an increased radial distance the metabolites must diffuse from each capillary, a situation which may conceivably lead to decreased nutrition and anoxia of the muscle fibers.

Fig. 1.—The relationship of heart weight to the creatine content of the left and right ventricles of the human heart in 195 autopsy cases.

It is difficult to obtain accurate information upon the effect of hypertrophy on the chemical composition of human heart muscle because of the variability of the findings and the influence of other factors. Cowan⁸ observed that in hearts with hypertrophy the average creatine concentration was slightly higher than in hearts without hypertrophy, but did not believe the slight difference to be significant.

In work carried out on human and animal hearts in this laboratory we have persistently noted a tendency toward higher creatine, phosphorus, and potassium values, with increases in heart weight. These differences, however, have been relatively small and of such magnitude as might be expected from variations in the amount of intracellular phase in the myocardium. The correlation between heart weight and chemical composition was most evident in cases of sudden death and in the hearts of dogs where the heart weight-body weight ratio was used as an index of hypertrophy (Mangun and Roberts, unpublished data). Most of these hearts, however, were within the range of what

is considered to be physiologic hypertrophy. To observe more closely the correlation between heart weight and creatine content throughout the normal and pathologic range, we have arranged the cases studied by Seecof and co-workers²⁷ and Mangun and associates^{22, 23} according to heart weights (Fig. 1). It is seen that the creatine content of both ventricles is low in hearts weighing less than 50 Gm. It rises rapidly, reaching a maximum in the left ventricle in the 51 to 150 Gm. hearts, and in the right ventricle in the 151-250 Gm. hearts it maintains its highest level up to 350 Gm., and then begins to fall, reaching its lowest level in adult hearts in the group weighing over 650 Gm. It should be pointed out that one should not lose sight of the effects of age and the incidence of myocardial insufficiency in these groups. The low heart weight group is composed of very young persons, less than a year old, and the incidence of heart failure increases progressively with each increment of heart weight. Relatively high creatine values are frequent throughout the range of heart weights, indicating that hypertrophy itself does not necessarily limit the saturation level of the muscle. Nevertheless, the fact remains that there is a statistical correlation between cardiac creatine content and heart weight.

SIGNIFICANCE OF THE CHEMICAL CHANGES IN HEART FAILURE

It has often been stated by clinicians that the observed changes in heart muscle in congestive failure were most likely due to anatomic changes in the muscle and, therefore, possessed no significance beyond a reflection of these anatomic changes. However, recent studies on electrolytes and water, connective tissue, fat, and other constituents of the heart indicate most clearly that the pronounced loss of creatine in myocardial failure cannot be explained upon that basis. There is a much greater per cent decrease in the concentration of creatine than can be explained upon any basis, except that part of the creatine has been lost from cells that are still retaining their identity insofar as the electrolyte pattern is concerned. In our experience, we are led to believe that a considerable part of the electrolyte changes occurring in failing hearts may be due to the intracellular disturbances in the phosphorus compounds, notably phosphocreatine and adenylypyrophosphate, with a concomitant extracellular edema or possibly a diffusion of extracellular electrolytes and water into the cells. As pointed out by Hastings and his collaborators,¹⁵ the present evidence permits either interpretation of the observed facts.

There is now evidence to indicate that simple cardiac hypertrophy is not responsible for the chemical changes observed in failing hearts. On the contrary, there appears to be an increase in the creatine content of the heart, and of other intracellular constituents, at least until a marked degree of hypertrophy has been attained. These changes may be due largely to an increase in the intracellular phase without a parallel increase in extracellular phase.

It should be stressed that the chemical events which we have observed in myocardial failure and experimental aortic insufficiency are those which have also been found to occur experimentally in cardiac and voluntary muscle as a result of anoxemia and fatigue. These aspects of chemical heart failure have been discussed in considerable detail by Herrmann and his co-workers. The role of hypertrophy in effecting a possible deleterious influence on the blood

supply and gaseous and nutritional exchange of the heart has been the subject of numerous experimental studies by Roberts, Wearn, and Badal,²⁶ Herrmann and collaborators,¹⁶ and others.

At the present time there appears to be no specific application of our knowledge of the chemistry of the heart which can be applied to the treatment of myocardial insufficiency. Nevertheless, there is a definite relationship between the chemical events in the heart and the therapy applied to congestive failure. Let us visualize the chemical system in the heart as a series of reactions designed to transfer energy from the substances carried to the muscle into mechanical energy of contraction. The ability of the heart at any given time to contract will depend upon the summated result of all the factors that contribute this energy versus all those factors which tend to dissipate, consume, or interfere with the production. So far as we know at the present time, phosphocreatine and adenylypyrophosphate are the two substances most closely associated with the final stage in the transfer of chemical energy to mechanical energy. To build up this final reaction to its highest level, the internist is, therefore, interested in accomplishing two objectives: increasing the rate at which energy is made available and decreasing the demands upon the system. In other words, we are interested in maintaining the optimum concentration of phosphocreatine and adenylypyrophosphate and yet having it supplying energy at an adequate rate, with the least possible dissipation. In the compensated heart the relative rates of the reactions centering about the phosphocreatine-adenylypyrophosphate system are such that energy input and energy expenditure are in equilibrium at a point where adequate amounts of phosphocreatine and adenylypyrophosphate are present. It is the task of the internist to maintain or improve the physiologic conditions which preserve this equilibrium.

At the present time most of the established methods of treating heart failure are probably effective largely because they decrease the demands upon the heart, thus permitting the energy input to keep abreast of the expenditure. The most outstanding of these types of therapy are rest, digitalis, and the removal of edema through regulation of the water and electrolyte balance. The latter may exert some direct beneficial effect upon the myocardium by removing edema fluid from that tissue, thereby accelerating the metabolic transfer. The possible direct action of digitalis upon the heart muscle still remains a subject of controversy. However, by overcoming tachycardia and irregularities of the heart it may decrease the expenditure of energy and increase the efficiency, a highly desirable effect from a chemical viewpoint.

While it is generally believed that the fundamental causes of decompensation may be attributed to increased demands upon the heart to perform work and decreased ability to perform such work as a result of disturbances in the coronary circulation, these considerations should by no means limit the possibilities of bolstering the heart action by measures directly affecting the myocardium. Attempts have been made to increase the creatine content of the heart experimentally or to prevent its loss by its addition to perfusing fluids, but these measures have met with little or no success. Similar attempts to increase the intracellular electrolytes of patients by feeding dipotassium phosphate have likewise met with failure.¹⁰ Decherd and Herrmann¹² have studied

the effect of various amino acids on the creatine content of the perfused rabbit heart. Only *DL*-alanine appeared to have an effect, and it seemed to act as a creatine-sparing substance. Glycine, glutamic acid, arginine, aspartic acid, methyl guanidine, and creatine had no such effect. Kalter¹⁹ administered glycine to patients with heart disease and reported a number of cases in which it apparently exerted a beneficial effect. Herrmann and Decherd¹⁶ have also reported some cases in which the administration of glycine appeared to have encouraging effects. Such studies are difficult to control, and the interpretations should be very cautious, due to the variability of such patients even without therapy.

The experimental finding that adenylypyrophosphate suffers a severe loss in anoxemia and fatigue,⁵ and in late aortic insufficiency,^{2*} and that there is a decrease in the extractive purine content of the human heart in myocardial failure²¹ suggests that disturbances in the metabolism of this compound may be of considerable significance. According to Lohmann's reaction:

phosphocreatine and adenylypyrophosphate exist in muscle in equilibrium with one another, the phosphocreatine acting as a donor of phosphate to maintain the nucleotide in a full state of phosphorylation at times when the transfer of phosphate from phosphopyruvic acid is inadequate. In the failing heart this mechanism may not suffice and there would be not only the depletion of the two compounds, but also the probability that a considerable part of the free adenylic acid would be deaminized to inosinic acid and thus removed from the system until reamination could be effected. It would appear that this problem should be investigated, and if this deamination does occur, it might prove of great value to learn more about the mechanism of reamination of inosinic acid to adenylic acid, and the effect of amino acids and other compounds upon this reamination. At present this is purely speculative and must await experimental investigation.

Finally let us emphasize that a decompensated heart, though it may be rendered capable of performing a limited amount of work sufficient to maintain the patient in a state of rest, cannot be considered to have recovered, from a chemical point of view, until a complete restitution of the chemical mechanism has been effected. Chemical deficiencies of the myocardium associated with, or resulting from, myocardial insufficiency must certainly constitute limiting factors in the process of recovery.

The chemical substances discussed in this paper by no means encompass the whole realm of possibilities. The number and variety of compounds concerned with the metabolism of the heart are constantly expanding, and new facts are being uncovered which throw light upon the question of how carbohydrates, fats, and proteins, their intermediate products, both in aerobic and anaerobic conditions, supply the energy of contraction. It is indeed possible that somewhere along the way we shall uncover information leading to a direct attack upon the complex problem of myocardial failure.

KIDNEY PARENCHYMA, CIRCULATING BLOOD PLASMA, AND TISSUE FLUIDS IN DIURESIS*

GEORGE HERRMANN, M.D., GALVESTON, TEXAS

THERE has been an increasing interest lately in the problems of the appearance of edema and of its dissipation by therapeutic measures. The development of new agents and of combinations of diuretics based on modern conceptions of different points and modes of action of the various types of drugs has been responsible for much progress in this field. On the European continent an agent is considered as a diuretic only when it increases the urinary output to the extent that there is a gross decrease in the body weight. Under the influence of Addis,¹ in this country we are content to speak of a diuresis when, as a result of the exhibition of a given therapeutic measure, there is a rise in the urinary output from less than 1 c.c. to 3 c.c. or more per minute, an increase of at least 100 per cent. The urinary output rises sometimes as high as 5 to 10 c.c. per minute at the height of the drug effect. However, a full explanation of exactly how diuresis is produced is not yet forthcoming. Nollenbruch² has discussed exhaustively a great number of the theories of water metabolism and diuresis, certainly many of which are still quite abstruse. A tremendous amount of research, experimental and clinical investigation, has been vigorously pursued in these fields in many attempts to establish the mode of action of diuretics.

Our clinical studies³ prosecuted during the past decade with mercurial and xanthine diuretics and combinations of the two drugs have yielded some interesting theoretical as well as practical information. The comparison of diuretics is a simple subject about which much has been written, while the theory of diuresis is complex and justifies further discussion. Clinicians must not lose sight of the fact that a great volume of work has been done in each chapter and each subchapter of water and salt exchange. The phases touched upon have been numerous. Studies have encompassed water intoxication; the extrarenal storage and relinquishment of fluids and electrolytes; the surrender of water by the interstitial tissues; the role of the tissues; the role of the liver; the water and salt balance; the water passage through the tissues; the genesis and significance of tissue edema; water retention and diuresis effected by sodium chloride; the plasma volume, electrolyte concentration; albumin and globulin levels and ratios and colloid osmotic pressure and viscosity; possible effects of water, mercurials, and xanthines on electrolyte and plasma protein balances; the role of the capillary walls and intracapillary blood pressure; tissue fluid pressures versus colloidal osmotic pressure; the circulation and kidney function; systemic blood, venous, capil-

*From the Department of Medicine of the University of Texas, Galveston.

lary, and glomerular pressures and blood flow as factors in diuresis; the blood constituents in relation to renal function; the kidneys functioning as the excretory organ. Many other questions have been studied. Literally hundreds of investigators have attacked these problems and sought to elucidate the complicated mechanisms. Unfortunately, much of the conflicting older experimental data had been obtained from studies on rabbits. Rabbits have been known to be notoriously susceptible to confusing nervous shifts in physiologic processes. Most of the diuretic experimental work must, therefore, be verified on large dogs before it can be accepted.

ANATOMICAL KIDNEY UNIT AND ITS PHYSIOLOGIC RELATIONSHIPS³⁻⁷

Into the uppermost end of each of one and one-half millions plus nephron tubules, afferent arterioles coil into an expansive network, invaginating the delicate epithelial layer of Bowman's capsule forming the broad filtration surface of the glomerular tuft. The surface area of the glomerular capillary bed is calculated to be about 1,000,000 square millimeters. Of similar importance is the anatomic fact that the efferent arteriole from each glomerulus follows the renal unit pattern and breaks up into a capillary bed in intimate contact with the continuation of the nephron, the epithelial-lined proximal and distal convoluted tubules. Some few direct vessels to the tubular plexuses have been found by MacNider to be present in diseased kidneys. Through these units the blood is brought into contact with the epithelial cells of a semipermeable membrane. The cardiovascular renal system tends to maintain a remarkable constancy in the general bodily milieu or homeostasis. Some water and some salts are eliminated to maintain the osmotic balance and the acid-base equilibrium, and the nitrogenous waste products are removed from the blood and discharged from the body. Glomerular filtration and active tubular reabsorption are now generally considered to be most significant factors in the maintenance of normal water and salt exchange. A consideration of the anatomy, and particularly of the blood supply of the nephron, makes it obvious that when the glomerulus fails in function, the tubule follows suit closely.

THEORIES OF KIDNEY FUNCTION^{4-6, 9-11}

The theories of kidney function have undergone changes since 1842 when Bowman postulated that water was secreted by the glomerular tuft and that the uriniferous products were secreted by the tubular epithelium, added to the water, and collected by the ducts as the urine. Ludwig in 1844 contended that production of urine consisted in the mechanical filtration of a protein-free solute through the glomerular membrane and reabsorption by diffusion of some salts and water. In 1874 Heidenhain revived the vitalistic secretion theory, adding that in addition to water, chlorides were selected and secreted by the glomerular epithelium, while organic nitrogenous waste substances and dyes were secreted by the lining cells of the tubules.

Barcroft and Straub¹⁰ in 1910 replaced blood plasma with Ringer's solution, retaining the red blood cells to insure oxygenation, and perfused this through intact kidneys with the production of an augmented urine flow without a rise

in blood pressure. Kuowilton in 1911 found that the addition of a colloid as gum acacia to the plasmapheresed erythrocyte solution or to a hypertonic glucose or saline solution introduced intravenously prevented a diuresis. Cohnheim in 1912 demonstrated that glomerular membrane cells had no selective secretory function, for if the body was deprived of salt, sodium chloride still appeared in the glomerular filtrate and had to be conserved by tubular reabsorption.

Cushny in 1917 conceived of a purely physical glomerular ultrafiltration and a nonvital selective diffusion tubular reabsorption. The plasma protein-free glomerular filtrate was postulated to be identical in electrolyte composition with plasma, contained water, salts, particularly sodium chloride, and also urea, uric acids, amino acids, creatinine, creatine, and glucose. While the tubular epithelium permitted diffusion through it of those threshold substances useful in the body economy and in maintaining water balance, there were reclaimed by tubular reabsorption all of the glucose, amino acids, and some of the salts and water. Cushny vehemently opposed every suggestion of tubular excretion.

Starling, as early as 1899, demonstrated the osmotic pressure of blood colloids to be 30 mm. Hg by preparing a filtrate of blood plasma through a gelatin filter, and with Verney in 1924, he added to Cushny's conception the theory of tubular secretion of dyes and urea, later confirmed by Hober and Marshall in 1930. Richards between 1910 and 1924, and his students between 1924 and 1938, by capsular and tubular microcatheterization proved the glomerular filtrate theory of Cushny's to hold and the actual specific reabsorption of various substances by the proximal and others by the distal convoluted tubules.

Rehberg in 1926 agreed to the glomerular filtration of a dilute dialysate of the blood plasma, but he too would endow the tubular epithelium with power of discrimination in reabsorption. He considered a substance threshold only if the percentage in reabsorbed fluid, under certain conditions, was higher than in the blood. Creatinine alone he accepted as entirely a waste totally nonthreshold substance, with phosphates, calcium, and sulfates as possibly so.

Homer W. Smith and associates, particularly Shannon in 1935, demonstrated the fact that creatinine was not an absolute index of glomerular filtration, but was apparently added by the tubular epithelial cells. In addition, urea, dyes as phenol red, and organic iodine preparations as hippuran, diodrast, skiodan, opax have been proved to be added by tubular excretion. D-xylose, raffinose, sucrose, and inulin were found to be the best indicators of glomerular filtration. The current theory generally accepted considers the glomerular fluid to be a simple filtrate of the blood plasma minus the serum proteins and fats similar to that passed through a gelatin filter from a colloid salt solution. The human tubular epithelium then enters into active selective reabsorption of water and substances to be conserved and probably adds to the concentrate urea, creatinine dyes, and organic iodide compounds.

Any consideration of the functions of the kidney must be concerned with the multiple extrarenal factors, blood plasma, electrolytes, nitrogenous waste,

colloids, intravascular and tissue pressures. Excretion of urine has been stopped when pressure in the ureter was raised to about 90 mm. Hg, with the blood pressure of 130 mm. Hg giving a differential pressure of about 40 mm. Hg. Dilution of the colloids in the plasma by adding urea, ammonium or potassium chloride or nitrate by mouth, or hypertonic glucose or injection of inert sugars and salt solutions by vein, draws water and salt from the tissues, lowers the pressure of the colloids, and inaugurates increased filtration and urine output. Changes in the circulation as congestive failure with anoxemia and in acute shock have been observed to produce oliguria or anuria. Water balance disturbances by dehydration by diarrhea, vomiting, or sweating decrease the urinary output considerably.

SIGNIFICANT CHEMICAL CONSTITUENTS OF BLOOD AND URINE

The blood plasma and dilute and concentrated urine content of the more common substances are of interest. For instance, the water percentages for blood plasma are 90 to 93 per cent as contrasted with 93 and 95 per cent for dilute and concentrated urine; the chlorides 0.370 Gm. per cent as contrasted with about 0.500 and 2,000 Gm. per cent; urea 0.030 Gm. per cent as contrasted with 2,000 and 6,000 Gm. per cent; uric acid 0.004 Gm. per cent as contrasted with 0.050 and 0.120 Gm. per cent; creatinine 0.001 Gm. per cent as contrasted with 0.075 and 0.750 Gm. per cent. Creatinine and creatine are related to the muscular development and are constant for the individual, hence only the percentages shift. Ammonia is increased with increased acidity of the urine, and a high protein diet increases urine acidity and ammonia and unidentifiable rest nitrogen. Ammonia increases also with nitrogen intake. Undetermined rest nitrogen amounts to between 2 and 12 per cent. A high protein intake of 100 Gm. per day yields a nitrogen output of 14 to 16 Gm., of which 80 to 90 per cent is urea. A low protein diet of 30 to 40 Gm. yields 4 Gm., of which 60 to 70 per cent is urea.

The inorganic salt metabolism and acid-base equilibrium concern chiefly sodium chloride as sodium and as chloride. Potassium, calcium, magnesium, carbonic acid, phosphates, and sulfates are of some significance, while copper, zinc, and foreign substances as thiosulfates and sulfocyanates play very minor roles. The sulfates though likewise unimportant are found in inorganic ethereal, organic acids, protein amino acid, cystine, cysteine, and neutral sulfur. According to Gamble, the bases in milliequivalents per liter as Na 142, K 5, Ca 5, and Mg 3, a total of 155, are balanced against the acid total of 155 made up of HCO_3 27, Cl 103, HPO_4 2, SO_4 1, organic acids 6, and protein 16.

The great reservoir of body water is the intracellular fluid; it represents about 50 per cent of the body weight. The intracellular fluid contains as its chief basic ion potassium and as its chief acid ions organic phosphates. The interstitial fluid makes up only 15 per cent of the body weight and differs in that sodium is its chief basic ion and chlorides constitute its chief acid ions. The interstitial fluid is more easily mobilized. The blood plasma amounts to only 5 per cent of the body weight but it is most active in water metabolism and presents evidence of very delicately controlled acid-base and electrolyte balances.

CIRCULATING BLOOD PLASMA

The kidney has two important functions to perform. It must regulate the salt and water exchanges so as to keep the osmotic pressure of the blood constant in addition to removal of the nonvolatile, nonprotein nitrogenous waste products of protein metabolism. The normal circulating blood plasma exhibits a delicate balance of electrolytes and colloids in equilibrium with those of the fluids of the interstitial tissues. A balance is normally established between the extruding intravascular blood pressure and the in-sucking osmotic pressure of blood colloids.

Blood plasma proteins are retained by the normal semipermeable glomerular membrane, while water and electrolytes filter through into Bowman's capsule in equimolar concentrations. The dilute glomerular filtrate is concentrated a hundred fold as the water, glucose, and some of the other constituents pass back through the epithelium of the convoluted tubules and the loop of Henle and through the walls of the distal capillary bed into the circulation. The increase in circulating blood plasma volume per se does not increase the urinary outflow.

Regulation of the kidney function by changes in the make-up of the blood has been demonstrated following electrolyte and colloid shifts. These slight changes in the blood plasma have been found promptly balanced by greater shifts of electrolytes and water from the interstitial tissues. Normal urinary constituents and other acid salts have been used to cause an increase of the plasma electrolytes to upset the electrolyte equilibrium and inaugurate an inflow from the tissues which in turn precipitates an increased urinary output.

CIRCULATORY FACTORS IN KIDNEY FUNCTION

Normal kidney units require an active adequate circulation as well as an expansive capillary bed in order to provide a sufficient filtration volume area. At the same time, however, there is a good deal of evidence that something more than physical processes is going on in the kidneys. Work is actually accomplished. Oxygen is utilized in renal metabolism, hippuric acid is synthesized from glycine and benzoic acid, and ammonia is formed. Utilization of oxygen by the isolated kidney in considerable amount with carbon dioxide formation has been demonstrated experimentally in the blood and by microanalyses. Oxygen consumption by the isolated kidney is considerably greater under conditions of increased activity. This has not been demonstrated in human beings. In fact, the ingestion of large amounts of fluid by normal individuals has been found by continental physiologists to produce a diuresis without a demonstrable increase in the general oxygen consumption. The forced fluid intake results in an increase in the minute output of the heart by an increase in the stroke volume with actually a decrease in the pulse rate and in the venous pressure and only a slight rise in the arterial blood pressure.

The renal parenchyma is in close physiologic relationship to the circulatory system and seems to be of the utmost importance in maintaining the constancy of blood plasma composition. The kidneys, by virtue of the

tremendous blood flow through them, constitute one of the four most vital capillary systems of the body. The vascular and renal systems are physiologically interdependent, the kidneys, perhaps playing the major role, but requiring nevertheless for this the maintenance of a quarter of the normal total blood flow. In the kidney, constriction of the afferent or the efferent arterioles of the glomerular tufts is possible and may affect the function oppositely.

In congestive failure of the circulation venous stasis increases the outflow from the increased volume blood plasma of water and salt into the tissue interstices. There are several other factors besides retention of salt and water in the tissues at work in causing oliguria. A decreased filtration through the glomerulus results from intraglomerular capillary pressure decrease with the usual fall in the systolic arterial pressure, in spite of the increased blood volume and the usually decreased blood colloid oncotic pressure. Tubular reabsorption remaining normal, the water content of the circulating blood increases. The general circulation may be improved by cardiac tonics and other measures, and diuresis results. The local circulation through the glomerular capillary tuft of the kidney may be influenced by drugs to dilate proximally or distally, or to contract likewise and in such changes of blood flow affect filtration or reabsorption.

Diuretic drugs, by changing the glomerular blood flow, upset the electrolyte balance³ of the blood plasma. This change seems to command a rapid mobilization of salts, and secondarily, fluids from the tissues, and transport to the kidney for excretion in a diuresis. The accumulated abnormal amounts of water and salts in the tissue interstices, the edema of the failing circulation, is thus dissipated. In the treatment of heart failure cases with oliguria the cardiac glucosides as digitalis improve the myocardial tone and the circulation thus evidently indirectly increasing the urinary output.

The primary regulation of kidney function by circulatory shifts *per se* has been repeatedly denied. Experimentally diuresis has been inaugurated and suspended with the maintenance of a constant blood pressure level. A pulse pressure change in the circulation may be the chief influence in modifying kidney function. Nonnenbruch felt that the filtration theory of renal function has exaggerated the significance of circulatory changes and the effect of arterial, capillary, and venous blood pressures on salt and water balance. He admitted that the abnormally high susceptibility of the renal arterioles to stimulation might result in contraction or dilatation, but this has not been proved experimentally as a significant factor in urine production. Many studies on the capillary bed in general physiology have revealed striking independence of the capillary flow of the size and of the tension in the arterioles. The status of the capillary bed, as a whole, may be significant. At the extreme limits the capillary flow must undoubtedly affect urinary output.

The effect of heat on the kidney, and particularly on its blood flow, has interested clinicians who have accomplished an increase in urinary output with diathermy in patients with anuria. Denervated kidneys have not responded in the same way. Cold did not produce exactly the opposite effects.

It seems that the effects are the results of reflexes. These reflexes in the case of heat, it is stated, do not result in increased circulation and yet there was increased urinary flow. In acute nephritis the high blood pressure is associated with oliguria and lower levels with increased urinary flow.

There may be quite a group of other variable factors effective in changing urinary flow, yet diuresis is not independent of an increased renal blood flow; in fact it needs it. The two go hand in hand, but we may have increased flow without diuresis, and diuresis without increased blood flow may be the result of the increased excretion of salts and water or decreased reabsorption. Chemical influences may cause a dilatation of the afferent or efferent glomerular arteriole and allow increased circulation or a constriction of the same with opposite effects. Frequently a prompt increase in the blood flow through the kidney is the primary response in its complicated activity.

INTERSTITIAL TISSUES

In order to explain the relatively ametabolic gross changes represented in water and salt shifts, the vastness of the capillary bed in the interstitial tissues all over the body, as well as in the kidney, must be taken into account. Krogh⁷ has estimated a capillary system of 10,000 meters in length and 63,000 square meters in surface area. In such a system the rapid exchange back and forth between the important electrolytes and fluids in the intercellular tissues and the blood plasma may easily be visualized as taking place rapidly as purely physical phenomena. Anoxemia or injury of the capillary wall of a significant segment of the system would cause edema formation. It has been estimated that the water content of the plasma changes about a hundred times a day, and that the whole water mass circulates throughout the body and makes a complete circuit probably six times each day.

The interstitial tissues and connective tissues form a very large extracellular reservoir or depot for the body fluids, salts, and other constituents. The capillary walls are single-cell semipermeable membranes through which water and electrolytes seem to pass back and forth freely. The colloid serum proteins, on the other hand, are held back completely in the normal glomerulus. It is evident, however, from Calvin's data on the blood plasma protein shifts during diuresis and following hydremic plethora, that in some areas the capillary walls permit the passage of serum proteins out of the tissue spaces into the blood plasma. The general rich capillary distribution makes possible the maintenance of equilibrium with relatively prompt return to the constancy of the blood plasma volume and its constituents.

NERVOUS AND HORMONE FACTORS^{10, 13}

Angioneurotic edema, allergic effusion, diabetes insipidus and its control with pitressin, myxedema, and desoxyepiandrosterone plethora are evidences that the nervous system and the glands of internal secretion play important, albeit largely unexplained, roles in water metabolism. Studies of the antidiuretic effect of pitressin in patients with diabetes insipidus indicate that the hormone pitressin acts directly on the kidney in some still rather

obscure way which is not related to the blood flow. At the same time there is following injection of pitressin much interstitial tissue effect which cannot as yet be elucidated.

Diabetes insipidus may result from injury to the posterior lobe of the pituitary or the hypothalamic region and tissues of the midbrain or the diencephalon. The posterior pituitary body is apparently linked physiologically with the great nuclear nerve origins as the vasomotor and other significant vegetative centers in the diencephalon. These centers are all susceptible to nervous humoral and hormonal stimulation. There is no proof that there is a decrease in pitressin in the blood stream to cause the thirst and diuresis of diabetes insipidus. The antidiuretic effect of pitressin persists in spite of the continued ingestion of large volumes of water and the addition of vasodilating drugs. The reported findings of abnormalities in the cells of the anterior lobe of the pituitary following diuresis and the apparent dehydrating effect of thyroxin have suggested the possibility of an anterior pituitary thyrotropic hormone disorder in myxedema.

The relatively recently discovered sodium, potassium, and plasma water balance disturbances in Addison's disease cases indicate that the adrenal cortical hormone is a significant factor in salt and water metabolism. The striking water storage effect of the synthetic hormone desoxycorticosterone is a fact that invites further investigations.

It is thus evident that the problems of water balance and water metabolism, edema formation, and diuresis have been extensively studied from almost every conceivable point of view.¹² Water intake, urinary output, blood plasma volume, and tissue fluid pressures have been shown to be most significantly concerned. In absolute water metabolism a delicate weighing is necessary to take into account the water that is lost in insensible perspiration, in exhaled air, and in the stools. Shifts in the individuals' body weight as determined by ordinary balances may record grossly the dissipation of the tissue edema, but the measured output of fluids through the kidney is the chief clinical index we have used. Normally the whole process from absorption of fluid through the gut, transport through the tissues and in the blood plasma to the kidneys, takes place without significant changes in the blood circulation time, volume, or pressures.

OUR STUDIES³⁰

Rehberg's¹⁴ creatinine clearance method was used at first in our laboratory in our studies of the mechanisms of diuresis by various substances in patients with congestive heart failure and edema. In spite of White and Monaghan's support, we were influenced by Shannon¹⁵ and Smith to determine also D-xylose and inulin clearances before and after the injection of mercurial and xanthine diuretics and digitalis glucosides. We have recorded the concomitant effects of drugs upon the blood plasma, electrolytes, and colloids, the urine volume and constituents, and the calculated renal glomerular filtration and tubular reabsorption. The evidence we obtained pointed to a primary effect directly upon the kidney units of the diuretic agents, such as are used in clinical medicine. The xanthines increased glomerular filtration, possibly

by afferent vasodilatation, and the mercurials decreased tubular reabsorption, possibly by efferent vasoconstriction or mild toxic decrease in permeability of the tubular epithelial cells. The possible pharmacodynamic renal effects were held responsible for slight but sudden and significant primary upsets in the very delicate electrolyte and colloid pressure balance in the blood plasma. Such slight shifts in turn, it was postulated, were promptly overcompensated for from the depots in the tissues in which there was edema. Salt, water, and proteins were drawn into the circulation. Electrolytes and fluid were then transported to the kidneys for excretion. A striking augmentation of the diuresis could routinely be produced by a combination of the two types of diuretics, and the clearance studies revealed combined effects with usually the mercurial effects, namely, decreased tubular reabsorption predominating. The tremendously augmented diuresis may not always be an unmixed blessing. This will be discussed more fully under the blood volume studies which contribute further argument.

SODIUM AND CHLORIDE STUDIES

The effect of mercurials, particularly salyrgan, upon sodium and chloride excretion and ratios has been recently restudied by several observers. Volhard's pupil, Weingarten,¹⁶ in support of the importance of the tissue salt and water status, so aptly designated "Vorniere" by his chief, held as indisputable the hydropigenous property of the chloride ion.

Bua,¹⁷ after the effects of salyrgan in diabetes insipidus, concluded that the presence of chlorine was the sine qua non requirement for the diuretic action of organic mercury salts. Simmert,¹⁸ observing the effect of diuresis produced by organic mercurial in patients with and without edema, found increases in the sodium chloride (determined also as chlorine) with concomitant rises in blood plasma sodium chloride (determined also as chlorine) along with decreases in hemoglobin and erythrocytes. Hitzenger and Englemann¹⁹ noted in salyrgan diuresis augmentation of excretion of many inorganic and organic substances, but particularly of sodium chloride.

The sodium ion, however, was incriminated in tissue fluid retention by Presser and Stahl.²⁰ These investigators found that the edema-producing effect of sodium could be set aside by a balanced combination of potassium, calcium and magnesium ions. This is the basis for the development of substitute for table salt for edematous patients. Bruman and Jenny²¹ established good correlation between sodium excretion and the urinary output. Siedek and Znekerkandl²² demonstrated greater retention of sodium than of chlorine in the edema fluid and transudates in the pleura and peritoneum in congestive heart failure patients. In diuresis of such edematous cardiac patients there appeared in the diuresate a conspicuous excess of sodium over chlorine.

In an attempt to elicit the initiating factors, and those at work during the first five to six hours of diuresis, Decherd³ determined the urinary Na/Cl ratios before, hourly during, and as a follow-up, each twenty-four hours for several days after each of 25 diuretic experiments with aminophyllin, mereupurin, and salyrgan. The blood sodium remained fixed, but the urinary sodium conspicuously increased, usually not in the tremendous proportions

of the chlorine excretion, so that the Na/Cl ratios as a rule decreased. Occasionally, however, the reverse was noted and the Na/Cl ratio increased. In these studies neither the mercurials nor the xanthines showed consistent or characteristic effects on the Na/Cl ratio.

If the volume of urine, with its contained sodium and chloride, passed during the control hours, was subtracted from the corresponding figures after injection of the diuretic, a fair approximation of the excess of these substances mobilized from the tissues during diuresis was obtained. By assuming the edema fluid to be an ultrafiltrate of blood plasma, the excess amount of sodium and chloride that should be excreted, with the excess urine excretion of the same composition as the tissue fluid, was calculated. The values for sodium determined on this basis showed a good agreement with those actually found, while the actual excretion of chloride was in most instances greatly in excess of the calculated values.

BLOOD SERUM PROTEIN STUDIES

Shally,²³ after some confirmatory physiochemical studies, accepted the conclusion of Nonnenbruch and others that changes in the colloid osmotic pressure did not explain the movements of water in diuresis. However, he found an absolute and relative increase in the albumin fraction, lowered and unchanged globulin, and a drop in fibrinogen at the onset of diuresis in all cases. He tried the effect of salyrgan on blood serum *in vitro* and concluded that in the concentration it appeared in the blood after injection salyrgan produced no change in the serum protein. He noted that at higher concentration there was flocculation. However, in this country, Bieter and Wright²⁴ have demonstrated, with ultramicroscope, changes in the blood serum of patients who had received therapeutic doses of salyrgan.

In recent studies in our department of biochemistry and in our laboratory for clinical research, Calvin and Deeherd^{25, 27-29} have demonstrated increases in the total circulating plasma protein, specifically albumin. They noted two different types of blood plasma volume changes following the exhibition of digoxin, aminophyllin, and salyrgan intravenously in patients with congestive heart failure and edema. The rapidity of the shifts of plasma proteins into and later out of the circulation suggested that there must be some degree of back flow of proteins as well as salts and water through the capillary walls in some parts of the capillary bed, possibly in the liver.

PLASMA VOLUME STUDIES

Meyer²⁶ postulated as the basis for diuresis a physico-therapeutic water-freeing effect upon the tissue colloids. The resulting hydremic plethora was held to dilate the renal vascular bed and account for the actual outpouring of urine. A study of the blood plasma volume shifts, using the new accurate method of Gregerson, Gibson, and Stead, and modified by Gibson and Evelyn with Evans blue dye 1824, seemed highly desirable. It was fortunate for us that D. B. Calvin, our biochemical experimentalist, had been working with this method of blood volume determination for four or five years. During the past year Calvin, together with Deeherd, undertook laboratory restudies of

the problems of diuresis in edematous congestive heart failure patients. In addition to establishment of the plasma volume shifts, the packed erythrocyte volumes, hemoglobin contents, albumin and total protein levels, as influenced by various diuretic agents, were determined.

The trends of plasma volume shifts seemed very definite. In a large series of experiments with the mercurial salyrgan (2 c.c. of 10 per cent solution) there was practically always a concentration in plasma volume that seemed to parallel diuresis. In two instances in which there was no diuresis and somewhat delayed diuresis there seemed to be a tendency for the plasma volume to increase slightly, but as soon as there was an increase in urinary flow there was a concomitant fall in the plasma volume.

Comparable studies using aminophyllin (7½ gr. or 0.5 Gm.) intravenously revealed a strikingly different plasma volume response. There was uniformly a conspicuous early rise in plasma volume. During the time of the most profuse diuresis there was a characteristic tendency for the plasma volume to return toward the initial level. As the aminophyllin diuresis continued, there was a shift in plasma volume apparently dependent, in part at least, upon the balance established between tissue fluid mobilization and urinary output. The end result was usually a plasma volume lower than that initially observed.

Digoxin, 2 mg. intravenously, in patients in congestive heart failure caused a shift in plasma volume apparently according to the promptness and degree of myocardial effect. When there was an immediate response, the plasma volume decreased sharply, as the satisfactory urinary output developed. When it was delayed, the plasma volume remained practically unchanged or increased slightly, until diuresis was inaugurated at which time the plasma volume decreased. Concomitant studies on the total circulating proteins indicate that there is a source of serum proteins, chiefly albumin, that is readily available and that the serum proteins may be promptly stored in the tissues.

COMMENTS

These most recent studies still leave many old questions as to the fundamental mechanisms of diuresis unanswered and open up some new ones. There is, however, some further evidence of a significant difference of the actions of mercurial diuretics as contrasted with xanthine diuretics. The relatively huge shifts in blood plasma volume following intravenous aminophyllin might account for some of the beneficent effects of such therapy in vascular disease. At the same time one might question the advisability of inducing such striking volume increases in patients with already abnormally high blood volumes and other evidences of congestive heart failure. In such cases repeated small injections and aminophyllin would seem to be more rational therapy. This suggestion may well be superfluous and the result of oversolicitousness, since no accidents indicative of such a mechanism have been recorded thus far. Then too, the combination drug, mercupurin, is much more often used in edematous cardiac patients, and under such circumstances the mercurial effect predominates, and as with salyrgan in the presence of good, or even fair, renal function there is from the beginning a shrinkage in the blood plasma volume.

The newer and more accurate methods offer new avenues of approach to the relatively old fundamental problems of the *modus operandi* of diuretics. The problems must, however, be vigorously prosecuted by every promising method to the end that the questions that have been raised by the survey of the subject may be answered. The answers to the questions will help in the further rationalization of diagnostic and therapeutic procedures.

THE FUNCTIONS OF THE CAROTID AND AORTIC BODIES*

CARL F. SCHMIDT, M.D., PHILADELPHIA, PA.

THE functions of the carotid and aortic bodies have been covered by four reviews within the past year,^{11, 13, 17c, 29} and no striking discoveries have been made since the last of these was published. My justification for acceding to the request for another review at this time is the hope of adding something to the understanding of this special branch of physiology by treating it from a different viewpoint, viz., that of the historical perspective of the subject, the persons involved, their reasons (as far as I know them) for doing what they did, and the influence of the various contributions on the development of the subject. This is not the least interesting and important part of this recent chapter in experimental medicine, and although some of the persons and factors involved have already been mentioned,^{28c} none of the existing reviews have been compiled so that a reader not familiar with the subject can trace its development.

Prior to 1930 the functions of the carotid and aortic bodies were unknown. This was not a very serious lack because the only interest in these structures lay in the rare occurrence of a tumor of the carotid body and the still rarer performance of an investigation of the morphology and embryology of that tissue. Such studies² left unsettled the question of whether the carotid body is a nervous structure (a ganglion or a paraganglion), a secreting gland of the chromaffin type, a peculiar cavernous vascular structure (a glomus), or something else (simply a body). Numerous attempts had been made to demonstrate a physiologically important secretion in the carotid body or in tumors arising from it, but none of these were very successful.

The event that served to direct attention into productive channels was Hering's discovery¹⁶ that the slowing of the pulse which had long been known to occur when deep pressure is exerted in the neck is not due to mechanical stimulation of the cardioinhibitory fibers of the vagus, as had been supposed for many years, but to stimulation of special receptors localized in the expanded region at the origin of the internal carotid artery. He called this the *carotid sinus*, and the term has come into general use; it is perhaps noteworthy that Hering's original intention is said to have been to call it the *carotid bulb*, but he decided against this because of the previous existence of another bulbo (oeno) cardiac reflex. He found that the afferent pathway for this new reflex is the first (pharyngeal) branch of the glossopharyngeal nerve (now called the sinus, intercarotid, or Hering's nerve) and that the reflex consists not only of cardiac inhibition but also of decreased vasomotor activity, so that it is completely analogous to the depressor reflex from the aorta described sixty years earlier by Ludwig and Cyon. The two carotid sinus nerves and the two depressor nerves were found by Hering to constitute a functional unit, any two, or, given sufficient time, even one, of the four being capable of carrying on an adequate

*From the Laboratory of Pharmacology, University of Pennsylvania.

degree of functional activity; but when all are cut, heart and vasomotor center become excessively active and persistent tachycardia and hypertension result. Because the influence of these reflexes is to restrain the heart and the vasomotor center, Hering called the four nerves which carry them the "Blutdruckzügler," or check reins of blood pressure. Subsequent workers have called them the "Nerfs Frenateurs" (Heymans) and the "buffer nerves" (Samson Wright), implying the same sort of moderator activity. It is noteworthy, however, that since these nerves are now known to carry other impulses which are stimulant, these descriptive terms, while widely used, are not strictly accurate.

The work of Hering introduced a new element into discussions of the regulation of the circulation. It attracted widespread attention because it presented a new viewpoint and opened a vista of possibilities previously unknown. Thus, the conception that the vasomotor center possesses a high intrinsic "tone" and is kept from producing maximal vasoconstriction only by afferent inhibitory nerve impulses aroused in special stretch receptors in the carotid sinuses and aortic arch has obvious implications to sustained hypertension or hypotension, syncope, and other clinical problems.³⁴ The conception that the cardioinhibitory center is activated, not by changes in the pressure or volume of flow of blood through it, but solely by these same afferent nerve impulses, has important implications with regard to the mode of regulation of the activity of nerve cells, which is one of the most important questions in all physiology. The technical difficulties involved in experiments such as those of Hering proved, however, to be considerably greater than was anticipated, and for several years no significant progress was made.

During this time J. F. Heymans, Professor of Pharmacology in the University of Ghent, and his son Corneille were engaged in an investigation of various physiologic problems by means of the crossed-circulation technique. In one remarkable set of experiments²⁰ they found that the respiratory movements of the head of a dog—entirely separated from the trunk save for the vagodepressor nerves and kept alive by anastomosis into the carotid-jugular circulation of a donor animal—could be depressed by a rise and stimulated by a fall in blood pressure in the trunk of the animal, and could be stimulated by asphyxia, anoxemia, or hypercarbia, depressed by overventilation or increased oxygenation of the blood in the trunk. The reflex nature of these phenomena was proved by their absence when the vagodepressor nerves were cut. By further refinements and amplifications of their technique, they showed that the reflexes responsible arise from the aortic arch. They concluded that such reflexes are a factor of importance in the control of respiration.

The report of these studies was published in 1927. Meanwhile Danielopolu and his co-workers in Bucharest,⁵ stimulated by Hering's discovery, had carried out a number of experiments on dogs and human beings and had found that reflexes from the carotid sinuses can affect respiration as well as circulation. They claimed that reflexes can also be aroused here by chemical agents (increased carbon dioxide tension) as well as by changes in pressure. Moissejeff²⁴ also described respiratory effects from the carotid sinus. The experimental evidence presented by these workers was not very impressive, and while they undoubtedly antedated Heymans in calling attention to the existence of respiratory reflexes

from the carotid sinus region, their work might have had little influence upon subsequent events had it not come at a time when J. F. Heymans and C. Heymans had just finished the studies from which they concluded that reflexes from the aorta, aroused by changes in pressure or chemical composition of the blood, constitute an important and hitherto unrecognized factor in the control of respiration. The statements claiming a similar, though less well-defined, function for carotid reflexes therefore constituted a challenge to the Belgian workers which the latter were not slow to accept. It is noteworthy that Heymans, whose name is now inseparably linked with the carotid sinus as one of its most effective advocates and who was awarded the 1938 Nobel Prize in Physiology and Medicine in recognition of his contributions to better understanding of the part played by these reflexes in the control of respiration and the influence of drugs upon it, began his work in that field in hopes of disproving the things he subsequently proved. Incidentally, a similar motive has activated a large proportion of the others (including myself) who have followed Heymans in investigating carotid reflexes to respiration.

During the same period de Castro,⁷ in Cajal's laboratory in Madrid, was carrying out a series of morphologic studies of the nerve structures involved in this new reflex of Hering. He found that nerve endings of a peculiar type are present in the adventitial coat of the internal carotid artery in the expanded region near its origin, viz., in Hering's carotid sinus. He also found an abundance of similar nerve structures in the carotid body, and in his first paper^{7a} he concluded that this structure is probably a secreting gland innervated by the glossopharyngeal; his studies led him to believe that the sinus nerve of Hering is a branch of the vagus, not of the glossopharyngeal, the latter being concerned only with the carotid body (or gland). Further study,^{7b} however, led him to modify his conclusions; the nerve system of the carotid body now seemed to be afferent at least in part, and he suggested that it is probably concerned in the regulation of blood pressure, its function being similar to, though less striking than, that of the carotid sinus^{7b, p. 364}; he also suggested^{7b, p. 370} that it might be a "sensory organ specialized to perceive certain qualitative changes in the blood." Several other workers^{8, 21} concluded that the carotid body is the site of origin of Hering's reflexes, not the carotid sinus, but it was not until the work of Heymans and his collaborators had shown clearly for the first time that there are two distinct sets of carotid reflexes, viz., those aroused by pressure and those aroused by chemical factors, that the second suggestion of de Castro led to productive experimental studies and was proved correct. Heymans and his co-workers were able to separate the two types of sensitivity, retaining that to chemical influences while removing that to pressure, or the reverse, and other workers succeeded in demonstrating that the chemically sensitive region in the dog is located in the carotid body. (The literature on this aspect of the subject is cited elsewhere.²⁰) Thus, the true function of this structure was finally proved to be none of those previously attributed to it, but instead, a completely unique one, i.e., translation of certain chemical changes in the blood into afferent impulses stimulant to the respiratory, vasomotor, and cardioinhibitory centers. These results stimulated other studies of similar tissue elsewhere, and a number of aggregates of cells resembling the carotid body morphologically were found

in the aortic region.^{2, 26} One of these was shown by the physiologic studies of Comroe³ to be the probable site of the aortic chemoreceptors; it receives blood from a small branch of the transverse aorta in the dog, of a coronary artery in the cat, and nerve fibers from it join the vagodepressor trunk at about the level of emergence of the recurrent laryngeal. The function of the other similar structures in the thorax and in the coccygeal region still remains unknown.

The papers by Heymans and his co-workers dealing with carotid reflexes to the respiratory center did for respiratory physiology what Hering's papers had done for circulatory physiology, i.e., they introduced a new element into discussions of the control of respiration and led to a critical re-examination of beliefs that had gone unchallenged for many years. At that time there was no doubt among physiologists that the major element in the automatic control of respiration was the effect of metabolic products directly upon the cells of the center and that afferent nerve impulses were nothing more than a nonessential factor. There had been some disagreement as to the identity of the chemical stimulus, but this was compromised to the satisfaction of most physiologists when Haldane (who was the first to demonstrate the very great effectiveness of carbon dioxide) accepted the view that the common denominator in all aspects of the chemical control of breathing is hydrogen-ion concentration in the blood.¹⁵ On this basis there were some difficulties in explaining the respiratory effects of changes in blood pressure (the respiratory depression or apnea produced by a sudden rise and the hyperpnea produced by a sharp fall), but these found a satisfactory solution in Rosenthal's conception,²⁷ as revived by Winterstein²⁸ and Gesell,¹² to the effect that it is the concentration of chemical stimuli within the cells of the center that regulates their activity, and since these cells are alive and have a metabolism of their own, their activity can be modified by changes in the rate at which products of their own metabolism are removed by the blood stream. The apnea produced by an intravenous injection of adrenalin or the hyperpnea produced by sudden hemorrhage, histamine injection, or any other sharp fall in blood pressure was an important piece of evidence in favor of this conception of respiratory control. The hyperpnea of anoxemia, which at first glance seems difficult to explain in terms of carbon dioxide tension or hydrogen-ion concentration in the arterial blood (for both of these are apt to be reduced by anoxemia), was attributed either to a sensitization of the center to its normal stimulus (carbon dioxide or pH) by anoxemia,¹⁵ or to accumulation of lactic acid within the cells of the center because of incomplete oxidation of metabolic products therein.¹²

Heymans and his colleagues presented evidence which, if fully substantiated, would have discredited entirely the Rosenthal-Winterstein-Gesell conception of respiratory control and would have necessitated radical revision in Haldane's. They showed¹⁷ that a rise in intracarotid pressure causes reflex inhibition of respiration, and this, coupled with the similar reflexes²⁰ aroused by a rise in aortic pressure, led them to suspect that the respiratory effects of changes in blood pressure might be due entirely to reflexes from the carotid sinuses and aortic arch—a suspicion which they verified by seemingly irrefutable experimental evidence and concluded that the activity of the cells of the respiratory center is not demonstrably influenced by changes in its blood supply, at least over

the physiologic range. They also¹⁸ found that an anoxic hyperpnea (and hypertension), whether produced by decrease in the oxygen tension in the blood or by the addition of cyanide to it, is mainly, if not exclusively, reflex in origin; section of the carotid sinus and aortic (depressor) nerves greatly reduced or completely abolished the stimulant effects of anoxemia on respiration and circulation, thus indicating that accumulation of products of incomplete oxidation in the center cannot be the true explanation of these effects. Even changes in carbon dioxide tension and pH in the arterial blood were found to produce their effects in part through these reflexes. Although it was never claimed that the respiratory effects of these changes are dominantly or exclusively due to reflexes from chemoreceptors (that claim was reserved for anoxemia and for drugs such as cyanide, nicotine, and lobeline), it was nevertheless reported that reflexes play a part in them. Thus the extreme sensitivity of the respiratory center to minute changes in the carbon dioxide tension or pH in the blood, which was perhaps the best-known and most firmly established fact in the entire field of respiratory physiology, came under suspicion, and with it the entire Haldane conception of the control of breathing. (As a matter of fact, Heymans did not commit himself at the time as to whether the chemoreceptors or the center are more sensitive to carbon dioxide and pH. It was not until 1939 that his position on this point was clearly stated, and then he held^{17c} that the chemoreceptors are more sensitive, act more quickly, and are responsible for a greater share of the total response to these stimuli than can be said of direct effects on the center.)

These papers naturally aroused a great deal of interest among all who were working in the field of respiratory physiology. Since we²⁹ have recently reviewed the literature on this subject from the viewpoint of the adequacy of the experimental evidence, it is unnecessary to recapitulate here the list of contributions that have followed. For the sake of historical perspective, however, it is worth noting that, with the appearance of Heymans' first papers, these reflexes came to be a major interest in the two laboratories in this country (Gesell's and our own) in which the workers had gone furthest in committing themselves to the Rosenthal-Winterstein-Gesell conception of respiratory control, which now seemed to be completely invalidated by Heymans' finding that the respiratory center is unaffected by changes in its blood supply. The resulting contributions from Gesell's laboratory, as summarized elsewhere,¹³ leave that group in substantial agreement with Heymans in all essential respects, i.e., that the responses of respiration to changes in blood pressure are due to reflexes from the pressoreceptors of the carotid sinuses and aortic arch, rather than to changes in the blood supply of the center, that the sensitivity of the chemoreceptors to carbon dioxide and pH is of the same order as that of the center, and that the chemoreceptors contribute an important share to the regulation of respiration under all circumstances. The work in our laboratory also led from the start^{28a} to agreement with Heymans about the existence of the two sets of reflexes (from pressoreceptors and chemoreceptors) and the dominant importance of the latter in the respiratory and circulatory stimulant effects of anoxemia. From the start, however,^{28a} we have been able to show that the respiratory center is not always as insensitive to changes in its blood supply as it was in Heymans' experiments, and among the factors that might be concerned

in such variations an outstanding one seemed to be the state of the finer blood vessels supplying the center. To investigate this relationship, an examination of the intrinsic control of the cerebral circulation was begun and is still in progress; the bearing of the results so far obtained on the above question has been considered elsewhere.³² From these experiments we have come to believe that the insensitivity of the respiratory center to changes in its blood supply in Heymans' experiments was due to fortuitous experimental circumstances,³³ and, therefore, does not warrant the general conclusion that the Rosenthal-Winterstein-Gesell conception of respiratory control is invalid. We also differed with Heymans from the start in believing that the respiratory center is so much more sensitive than the chemoreceptors to carbon dioxide that the normal control of breathing is probably accomplished by the center alone, without involving the chemoreceptors. Subsequent experimental evidence has only served to strengthen this belief.²⁹

The present status of the questions raised by Heymans' work, in briefest summary, is as follows: There is general agreement about the existence of two sets of reflexes in carotids and aorta, the one activated by changes in arterial pressure, the other by changes in chemical composition of the arterial blood; the receptors responding to pressure (pressoreceptors) are located in the adventitial coat of the carotid sinus and aortic arch, those responding to chemical changes (chemoreceptors), in the carotid and aortic bodies; the impulses from both sets of receptors are carried by the same nerves (the sinus and depressor) and affect the same structures (the respiratory, vasomotor, and cardio-regulatory centers in the medulla), although for the most part in opposite directions, i.e., impulses from the pressoreceptors lead to *decreased* activity of the respiratory, vasomotor, and cardioaccelerator centers (and increased activity of the cardioinhibitory), while impulses from the chemoreceptors cause *increased* activity of all these centers (including the cardioinhibitory in the case of strong stimulation of the carotid chemoreceptors of the dog). There is also general agreement that the chemoreceptors can be stimulated by each of the chemical factors that have long been associated with the control of respiration and circulation, namely, increased carbon dioxide tension or hydrogen-ion concentration, or decreased oxygen tension, as well as by a variety of drugs and poisons (cyanides, sulfides, nicotine, lobeline, coniine, sparteine, choline and its nicotinic derivatives, acetaldehyde, potassium salts, dinitrophenol, dinitroresol, and others). It is also agreed that the reflexes from the pressoreceptors (which are those originally described by Hering) are of utmost importance to the control of the circulation, but of comparatively little moment to the regulation of respiration, whereas the chemoreceptor reflexes are of major importance to respiration, but are relatively unimportant to the circulation, with one significant exception, viz., the hypertension of anoxemia.

When it comes to an evaluation of the part played by these reflexes in the adjustment of the organism to its environment, differences of opinion are encountered. As indicated elsewhere,²⁹ these seem to us to be due to inadequacy of experimental evidence relative to the conclusions drawn, for the data needed for this purpose must be quantitative, and the step from the qualitative information that suffices to demonstrate the existence of these reflexes to the

quantitative data required to evaluate their importance is long and difficult. It is clear, however, that the hyperpnea and hypertension of anoxia are (as Heymans claimed from the start) due more to reflexes from the chemoreceptors than to direct effects on the center, and in my opinion, the burden of evidence indicates that anoxia is purely depressant to nerve cells, any stimulant effects being due to reflexes; this view is not shared by Gesell¹² or by Dautrebande,⁶ but it is supported by recent work done in Heymans' laboratory.¹ As for the part played by chemoreceptor reflexes in the body's responses to exercise or increased carbon dioxide tension or hydrogen-ion concentration, existing information²⁹ leads me to conclude that this is negligible under normal circumstances, but it can become very important when the sensitivity of the center to carbon dioxide is abnormally low, as in narcotic poisoning; this belief is not concurred in by Heymans and Bouckaert,^{17c} Gesell,¹² or von Euler and his collaborators.¹⁰ The point of fundamental importance here is the relative sensitivity of the center and of the chemoreceptors to carbon dioxide or pH, and the only quantitative data now available are those^{4, 20, 21} which have led us to the above conclusion. Another point of importance in deciding on the physiologic significance of these reflexes is the nature of the stimulus by which they are activated; it is perhaps inevitable that attempts should be made to simplify the situation by finding a common denominator for all chemoreceptor stimulations, and different workers have suggested increased acidity,¹³ anoxia,⁴ acetylcholine,²³ and potassium⁹ in this connection. In view of the diverse nature of the substances that have been proved capable of stimulating the chemoreceptors,²⁹ such attempts do not seem very profitable at this time; it seems better to conclude simply that these structures are so organized that they give rise to nerve impulses when the chemical equilibria of the cells are sufficiently disturbed, and that such disturbances can be brought about in a number of different ways. The question of the identity of the stimulus to the chemoreceptors is likely to assume greater importance in the near future in view of the recent work in Krogh's laboratory^{22, 25} leading to the conclusion that the chemical control of respiration is accomplished by carbon dioxide acting as such, not by virtue of changes in acidity produced by it. If this conclusion is correct, the respiratory effects of changes in pH of the blood could be attributed either to the changes in carbon dioxide tension produced by them or to reflexes from the chemoreceptors; perhaps these are the only parts of the respiratory regulating system that respond directly to the hydrogen ion.

My opinion of the significance of these structures agrees with that of Marshall and Rosenfeld,²³ who suggested that they represent a survival of a primitive type of control found in water-breathing animals. As noted elsewhere,^{4, 25b, 29} this conception is supported both by existing information concerning the regulation of respiration in fish²² and by the derivation of the carotid (and probably aortic) bodies from the same tissues that give rise to the branchial (gill) arterial system in the embryo.² It accounts for the great resistance of these receptors to the depressant effects of anoxia, for this is characteristic of embryonic tissues in general, and the carotid and aortic bodies presumably are relatively primitive, undifferentiated structures; perhaps their ability to be stimulated by anoxia and by great increases in carbon dioxide

tension and acidity, as well as by drugs and poisons that depress many other tissues, depends simply on their resistance to depression by these agents. This conception appears to be in better accord with available information than the alternative suggestion¹³ that these structures have the same functional characteristics and significance as the neurones of the medullary centers.

SUMMARY

The carotid and aortic bodies are structures whose specialized function it is to respond to changes in the chemical composition of the arterial blood by setting up afferent impulses which enter the central nervous system with the glossopharyngeal and vagus nerves, respectively.

The nerve impulses in question are stimulant to the medullary centers (respiratory, vasomotor, and, in the case of the carotid body of the dog, cardio-inhibitory). The impulses from the stretch receptors of the carotid sinuses and aortic arch (carried by the same nerves) are inhibitory to these centers (except the cardioinhibitory, which is stimulated by them).

The chemically sensitive receptors (chemoreceptors) can be stimulated by anoxemia, asphyxia, increased carbon dioxide tension, or increased hydrogen-ion concentration, or by a variety of drugs and poisons which have no common chemical or physiologic attribute although the list includes inhibitors of oxidations (cyanide, sulfide) and substances with nicotinic properties (nicotine, lobeline, coniine, and choline and its derivatives).

Reflexes from these structures are responsible for much, if not all, of the stimulant effects of anoxia on respiration and circulation. They probably are not concerned in the normal control of respiration, the sensitivity of the chemoreceptors to carbon dioxide being much less than that of the centers unless the latter is depressed; in that event these reflexes become an important factor in maintaining respiration.

An explanation that is in accord with existing information on the subject is that the chemoreceptors represent a survival in relatively undifferentiated form of a reflex mechanism originally developed for a water-breathing ancestral form. The ability of these structures to set up a strong reflex stimulation to respiration when exposed to an environment that would depress or paralyze nerve cells (severe anoxia, very high carbon dioxide tension or acidity, deep narcosis) is probably related to their primitive status and responsible for much, if not all, of their value to the organism.

EPILEPSY: NEWER METHODS OF INVESTIGATION AND TREATMENT*

WILLIAM G. LENNOX, M.D., BOSTON, MASS.

THE earliest medical writers speculated about the cause of seizures in epilepsy and prescribed meticulous treatments. From the time the well-known treatise on the subject was written by Hippocrates or one of his followers until the present time is a span of some 2,400 years. During nine-tenths of this period doctors were interested not in newer treatments but in older ones. They wanted to know what Hippocrates, Galen, and Aretaeus had to say about the Falling Sickness. Advances in knowledge have been prominent in three periods: First, about the end of the seventeenth century, Thomas Willis in England and Boerhaave in Holland began to look with their own eyes at the problem of epilepsy. Second, the latter half of the nineteenth century stands out because of the animal experiments of Kussmaul and Tenner, and Frisch and Hitzig, the school of English clinicians led by Hughlings Jackson, Gowers, Reynolds, and Sieveking, and the first use by Locock of an effective anticonvulsant drug, bromide. Third, is the present "new methods" period.

The progress of research in epilepsy has, in general, followed the development of clinical and laboratory techniques. Because physicians realized that seizures arose in the brain, anatomy, at first gross and then microscopic, was expected to answer the riddle of epilepsy. However, as long ago as 1859 Kussmaul and Tenner said: "The judicious physician will relinquish the hope that pathological anatomy is destined to give an explanation of the nature and seat of epilepsy, and he will only expect that result from the progress of the experimental physiology of nerves." Events have confirmed this prediction. It is now realized that demonstrable structural abnormalities of the brain are the results of seizures or else only a contributing cause. There may be certain patients, for example, adults with a tumor of the frontal or parietal lobe, in whom the pathology is the sole cause of seizures, but such cases constitute only an insignificant fraction of the total number of patients who are subject to seizures.

If the primary disorder is not anatomic, but a disturbed function of nervous tissues, then the specialized and intricate techniques used in chemistry, physics, and physiology must be called upon. However, medical science does not always advance along the lines of logical development; it may start from an unorthodox chance observation. Twenty years ago attention was attracted to an osteopathic practitioner who was treating patients with seizures by means of fasting, with, in some instances, dramatic results. The observation was empirical but sound, and the beginning of the third period mentioned may properly be marked—

*From the Department of Neurology, Harvard Medical School, and the Neurological Unit, Boston City Hospital.

Conklin, 1920. Geyelin¹ believed that the beneficial results of fasting may be due to the acidosis induced, and carried through a great volume of laboratory examinations which, unfortunately, he never published. Wilder² suggested that the acidosis of fasting could be induced also by a ketogenic diet which could be maintained for a longer period than fasting. Other workers at the Mayo Clinic,³⁻⁶ in Boston,⁷ in Baltimore,⁸ and elsewhere have demonstrated that ketosis is accompanied by definite improvement in many (about one-half) of the children treated. An inorganic acidosis, induced by ingestion of hydrochloric acid,⁹ of acid-forming salts, or by the inhalation of air containing 10 per cent carbon dioxide¹⁰ also proved to be temporarily effective in stopping petit mal. Rosett¹¹ and Foerster¹² precipitated attacks by the opposite condition of hyperpnea.

Changes in the acid-base balance of the organism are attended by widespread alterations in other physicochemical and physiologic relationships. The simple act of overventilation, which so readily precipitates petit mal, causes a constriction of cerebral arterioles, with resulting decrease in cerebral blood flow,¹³ and also alters the electrical conductivity of nervous tissues¹⁴ and the oxygen dissociation curves of the blood. Although the oxygen saturation of the arterial and internal jugular blood of epileptic patients is not abnormal, a sharp reduction in the oxygen tension of inspired air will bring on petit mal attacks,¹⁵ and a temporary increase in the oxygen tension up to twenty times normal will hinder attacks.¹⁵ However, prolonged exposure to still higher tensions will precipitate convulsions.

Working on the hypothesis that epileptics have an incomplete drainage of spinal fluid with resulting pressure on the cortex from the accumulated fluid, Fay¹⁶ proposed treatment by means of dehydration. Though the hypothesis was faulty, as others^{17, 18} have shown, the demonstration of positive effect of dehydration on seizures was valid. That the effect was chemical and not, as Fay had argued, hydrostatic, was indicated by the demonstration by McQuarrie¹⁹ that seizures could be precipitated by retention of body fluids induced by the injection of pitressin in association with a high water intake; if normal saline were substituted for the water, seizures did not result.

That convulsions in animals and patients follow the injection of an overdose of insulin has been known since that hormone was isolated, but the neurochemistry involved was conjectural. There seemed to be no pressing reason to pursue the problem until it was discovered that the induction of severe hypoglycemia seemed to improve the mental condition of patients with schizophrenia. Then therapeutic convulsions, induced either by insulin or metrazol or electrical shock, became fashionable, and gradually physiologists and physicians are beginning to grasp the heaven-sent opportunity to study the chemistry involved in convulsions induced in human beings. Apparently with the exhaustion of the glucose of the brain, glucose and oxygen consumption is reduced,^{20, 21} and in the eviscerated animal the only thing which will restore cerebral activity is glucose itself, and not one of its derivatives.²²

Although epileptics who have diabetes seem to have fewer seizures when the diabetes is worst, and though remissions in petit mal have been produced by an insulin-glucose treatment which makes patients worse and then better,²³ only

the very rare patient seems to have any error in sugar metabolism which is the direct cause of seizures. This rarity is the patient with adenoma of the islets of Langerhans.

A person cannot realize the importance of the physiologic investigations of recent years unless his view includes their drab background. One element in this background was present in both ancient and modern times, the belief that seizures might come from a suprabiological source. The Freudian conception that the subconscious might throw an individual into a convulsion in order to simulate an intrauterine existence seems to be allied with the ancient conception of an indwelling demon doing his malignant daily dozen.

However, great as these contributions were, the investigation of epilepsy threatened to bog down. The influence of many physicochemical changes on seizures had been demonstrated, but it proved to be easier to start seizures than to stop them. Acidosis induced by a ketogenic diet in children, or by means of physical exercise, and possibly dehydration therapy, seemed to be the only measures of clinical value. None of the dozens of researches on body metabolism and blood chemistry had shown any consistent abnormality in epileptics (except perhaps an inconsistency and instability of many metabolic functions).²⁴ Various chemical changes would produce seizures, but only in those persons already subject to seizures. Many chemical changes could be demonstrated in the body and blood as a result of a convulsion but none as a precursor. Chemical alterations in the urine or venous blood of the arm bore an unknown relationship to changes in the metabolism of the brain. Convulsions induced in animals were a poor substitute for the spontaneous convulsions of patients. Even the century-old theory that a cerebral vascular spasm produced cerebral anemia and thus set off a seizure lost its appeal when a thermoelectric flow recorder placed in an internal jugular vein failed to record any decrease in cerebral flow before the onset of a seizure.²⁵ There seemed to be no avenue which would permit study of the activity of the living human brain and research came to a dead end.

In spite of the boasted receptivity of our age to new ideas, statements made by Berger of Jena in 1929²⁶ and thereafter that he could record the electrical potentials of the brain through the intact skull and that alterations of these potentials occurred during epileptic convulsions were ignored by physiologists and clinicians alike. After several years, however, repetition of his observations was attempted and his claim confirmed. With respect to epilepsy, the use of Berger's apparatus, the electroencephalograph, opened not just a new chapter but a new volume in the study and treatment of this disease. The interest of research workers has been revived. The clinicians, instead of guessing from the actions of the patients what is going on in the brain, can watch the brain itself at work. The patient, inured through the centuries to painful experimentation, can sit in an easy chair and let his brain write its own verdict on the diagnosis and prognosis of its disorder. The results of the studies of Gibbs, Gibbs, and Lennox,²⁷ which have been carried on during the past five years and which in some respects have been amplified by others, may be summarized as follows:

1. Seizures are accompanied by profound alterations in the rate and in the voltage of the electrical pulsations of the cortex. This is apparently true in all

eases except in those persons whose seizures are under conscious or subconscious control; hysterical seizures are not accompanied by dysrhythmia. Nevertheless, changes in brain activity consequent on attention or sensory stimulation (especially optic stimulation) and on sleep greatly alter the waves.

2. Approximately 95 per cent of patients subject to epileptic seizures show abnormalities in the electroencephalogram in a record taken for fifteen or twenty minutes when the patient is free of symptoms.

Fig. 1.—Patterns of electroencephalographic tracings encountered in patients with epilepsy during various types of seizures; namely, grand mal, petit mal, petit mal variant, and psychomotor (psychic equivalent) seizures. In the psychomotor attack, *A* represents the onset and *B* a later phase of the seizure. These abnormal patterns may appear either with or without seizures which are clinically observable. In each case the curve represents the difference in potential of the cortex between an electrode attached to the left forehead and one attached to the ear. The signal at the right indicates the deflection caused by 50 millivolts or, in the case of petit mal, 200 millivolts current. The time marked by one second is indicated in the right lower corner. (From Gibbs, Gibbs, and Lennox²¹)

3. The different types of seizures trace distinctive patterns on the electroencephalogram; namely, petit mal seizures are associated with alternately fast and slow waves recurring at the rate of 3 a second; a slower, 2 a second, rhythm forms a variant, which is of particular interest because, unlike the 3-a-second form, it is not easily influenced by changes in the chemistry of the blood. Psychic seizures are accompanied by slow, high voltage waves, with oftentimes a square, crenated top. Grand mal attacks are accompanied by fast, high potential waves (Fig. 1).

4. In many patients coming grand mal attacks can be predicted by the increase in fast waves in the electroencephalogram for as many as eighteen hours preceding the attack.

5. In many patients the abnormal waves begin in a certain area, or waves in this area are more abnormal than elsewhere. If this area should be a frontal lobe with the dysrhythmia limited to it, lobectomy might prove beneficial.

6. In case of a cortical lesion, such as one caused by a tumor or trauma, electroencephalographic examination discloses abnormal waves at the periphery of the lesion.²⁸⁻³¹ The procedure is, therefore, useful to the surgeon in localizing lesions (whether patients are epileptic or not) which might require surgical intervention.

7. The rhythm of the brain is apparently a constitutional characteristic, for in spite of the many conditions which may modify the electroencephalogram, an individual who has a distinctive pattern tends to show this same pattern, either normal or abnormal, when his record is taken under standard conditions on successive occasions. The normal tracings of healthy similar twins are closely similar,³² as are the abnormal tracings of patients;³³ and a large proportion (60 per cent) of the relatives of epileptics, both of the essential and symptomatic groups, have abnormal electroencephalographic records.³³ Approximately 10 per cent of persons without a history of epilepsy in their immediate families have cortical dysrhythmia. Since approximately 0.5 per cent of the population have a personal history of seizures, these data indicate that there are approximately 20 persons with a dysrhythmia to one who has seizures, or in the United States 10 million persons who have a predisposition to epilepsy, or a related disorder, to half a million actual epileptics. These observations raise very large personal and social questions concerning possible prophylaxis against epilepsy among predisposed individuals and in the race.

8. Although epilepsy can now be spoken of as a cerebral dysrhythmia, it is only one of many. Dysrhythmia may be asymptomatic or symptomatic. If symptomatic, the associated manifestations may take the form of seizures, or periods of misbehavior as in "problem children,"³⁴ or in mental disorders.³⁵⁻³⁸ The borderlands of clinical epilepsy are ill defined. Cerebral dysrhythmia includes many of these borderland conditions. In epilepsy Gibbs³⁹ believes that when there is cortical dysrhythmia the primary disturbance is in the chemio-electrical oscillators of the brain. If a chemical regulator of the brain can be found, many types of dysrhythmia associated with clinical disturbances which now bear various names can be helped.

As an aid in the interpretation of records, Grass⁴⁰ has utilized the principle of the Fourier transform to build an apparatus for the analysis of records by electrical means. This analyzer summates the total energy contained in the waves of various frequencies, the faster of which are not easily detected in the ordinary tracings, and it also allows accurate comparison of the records of various persons, with respect to the amount of energy present in the various wave frequencies.

9. The rate and voltage of waves can be altered by changes in blood chemistry. This fact permits a resumption of the promising chemical studies of a decade ago. The investigator no longer needs to wait for the patient to have a

convulsion. He can watch the progress of the disorder on the moving paper tape. Observations with the electroencephalograph have confirmed previous clinical observations, for alkalosis, anoxemia, and hypoglycemia increase dysrhythmia. However, a previously undreamed-of opening for study has appeared in the fact that certain chemical changes in the blood can be correlated with certain variations in the rate of brain waves, and these with various types of seizures. Artificial reduction of carbon dioxide in the alveolar air and arterial blood slows the frequency of brain waves and is especially potent in precipitating petit mal which has an extremely slow 3-a-second wave. Increasing the carbon dioxide, on the other hand, speeds up brain waves and inhibits petit mal. Furthermore, and this seems especially significant, patients who have only petit mal tend to have a low concentration of carbon dioxide in the arterial and internal jugular blood, whereas patients who have grand mal tend to have an abnormally high value.⁴¹ This statement refers to blood taken at odd times, but in a few observations which have been made arterial carbon dioxide seems to fall before a petit mal and to rise before a grand mal. The evidence is not yet complete, because it has not been shown that overventilation will inhibit a grand mal and high carbon dioxide will precipitate it.

Efforts are now being made to evaluate the various factors in the acid-base balance of blood passing through the brain in their relationship to seizures and to dysrhythmia. In these studies a lumbar puncture needle is placed in an internal jugular vein and in a femoral artery, and blood samples are withdrawn simultaneously from these two vessels before, during, and after seizures, and with relation to procedures which alter blood chemistry and brain waves. So far these observations indicate that small changes in carbon dioxide are much more influential in altering the electrical activity of the brain than are changes in oxygen or glucose. The changes in cerebral blood flow which follow changes in arterial carbon dioxide seem to be for the purpose of protecting the brain against abrupt fluctuations of carbon dioxide tension.⁴² Studies of the nomograms expressing the relationships of the carbon dioxide content and tension and the pH of arterial and internal jugular blood indicate distortions of the nomogram in epileptic patients as compared with nonepileptic persons,⁴³ and after artificial changes in carbon dioxide level an abnormally slow return of the cerebral circulation to its former flow.

Obviously these investigations are but a step toward an understanding of the physico-electrochemical processes which are concerned in the discharge, normal and abnormal, of the neurones of the brain. However, the gateway to new adventures in the realm of fundamental factors in the activity of nerve cells is now open for those who have the technical knowledge, equipment, and money to proceed.

These investigations are aimed primarily at an understanding of the underlying etiology of epilepsy, the peculiar inherited characteristics of neurones which cause them to discharge in a manner inimical to the welfare of the individual. Electroencephalographic examinations are of practical value to the physician and patient in judging the severity of the dysrhythmia and its response to treatment, in localizing cortical lesions when these are present, and in tracing the descent of epilepsy and related cerebral disorders. These newer

studies have answered many questions which have troubled students, but they have added others. For example, why do some persons with dysrhythmia have symptoms and others have none? Can the physician be content with stopping seizures but not dysrhythmia? What must be said to normal persons who have no suggestive family history of epilepsy or migraine but who do have dysrhythmia? Epilepsy research factories have a "backlog" of orders for many years to come.

Of newer aids to therapy, sodium diphenyl hydantoinate (dilantin sodium) is outstanding. Putnam and Merritt⁴⁴ used a method similar to one employed also by Spiegel⁴⁵ for producing convulsions in animals by passing an electric current through the brain. The amount of current required to produce a convulsion could be determined for an individual animal and the effect of the various drugs in preventing convulsions could be evaluated. Merritt and Putnam⁴⁶ tested scores of drugs, several of which seemed to have a higher anti-convulsant value than either of the accepted anticonvulsants, bromides, or phenobarbital. One of these, sodium diphenyl hydantoinate, was put to clinical tests and has proved its usefulness. Experience has shown that for the majority of patients dilantin sodium is more effective in controlling attacks than other drugs, and it has a relatively slight hypnotic effect. It is much more effective in stopping psychic and grand mal than in stopping petit mal seizures. More careful supervision of the patient and the dosage is required than for bromide or phenobarbital. The amount given must be increased until satisfactory therapeutic results are achieved, or until unpleasant side actions occur. This means that many patients given this treatment will show one or more of these side actions, namely, gastric irritation, ataxia, skin eruptions, or hyperplasia of the gums. Persons not sufficiently helped by dilantin sodium alone may be given phenobarbital or phenobarbital and benzedrine. For the large number of patients whom the drug dramatically helps, the year 1938 will be a milestone, just as 1857 (bromides) and 1912 (phenobarbital) have been milestones for previous generations of epileptics. Though not of such widespread usefulness, the demonstration by Cobb and Cohen⁴⁷ that certain dyes exert an inhibitory effect on seizures is of much theoretical interest. Aird⁴⁸ suggests that the dye may clog the blood spinal fluid barrier and thus prevent supposed convulsive toxins from entering the brain. Experiments with animals are handicapped by the fact that animals have not been used (if indeed any exists) which have an underlying cerebral dysrhythmia and spontaneous seizures. Animals made epileptic belong to the so-called symptomatic variety. Nevertheless, convulsions induced in unanesthetized animals by electric shock, either direct or from remote excitation,⁴⁹ or by convulsant drugs, permit evaluation of measures which affect seizure threshold, and offer a means for following the neurologic pathway of a seizure.⁵⁰ More nearly approximating clinical conditions are cerebral lesions which in the course of hours or days are followed by apparent spontaneously appearing seizures. This has been accomplished through freezing small areas of the cortex by Speransky⁵¹ and through very high roentgen-ray exposures by Derbyshire.⁵²

Advances have been made also in special fields. The operating room, especially that of Penfield,⁵³ has been used as a laboratory for tracing in the exposed cortices of patients "trigger zones" of Jacksonian seizures and for

observing spontaneous vascular responses to cortical stimulation as well as those which follow it. Careful histologic studies of the brain have demonstrated that an area of necrosis caused by a small vascular or other lesion may grow larger over a period of months or years, thus accounting for the long interval which may elapse between a head injury and the first seizure.⁵⁴ Also, bold surgery has freed many selected patients of seizures due to tumor or trauma.⁵⁵

Part of the progress of research in epilepsy has been the elimination of groups of persons who rightfully belong in some category besides epilepsy. Many a patient labeled "hysterical" or "psychopathic personality" or simply "mean," can now be diagnosed as dysrhythmic and treated as a sick person instead of an emotional or bad one. Rarely has the person labeled "epileptic" been proved hysterical. Through the work of Weiss and his associates,⁵⁶ the physician is now able to sift from his epileptics the occasional patient whose seizures are due to an irritable carotid sinus and whose symptoms can be relieved by atropine, benzedrine, or by extirpation of the sinus. The study of migraine, which is genetically related to epilepsy,⁵⁷ has shown the importance of abnormal relaxation of the branches of the external carotid artery in the production of headache⁵⁸ and the dramatic relief of individual attacks of migraine which can be obtained by the injection of ergotamine tartrate.⁵⁹ Persons with narcolepsy have also been vastly aided by drug treatment with benzedrine sulfate.⁶⁰

Scientific advances in the understanding and treatment of epilepsy in the last twenty years have been prodigious, but public appreciation of the size of the social and economic aspects of the problem, and correction of the popular attitude toward persons with seizures have lagged far behind. Popular ignorance, fear, and prejudice are reminiscent of the Middle Ages. Gradually the public must learn that epilepsy is not necessarily or usually associated with mental deterioration, and that most epileptics, if given a chance, can be useful citizens. The problem of the ten million potential epileptics should not arouse fear, but a determination to learn more about epilepsy and dysrhythmia and their treatment.

As an experiment in this direction an organization called the "Laymen's League Against Epilepsy" has been formed. Anyone may become a member and pay either \$1.00 or \$5.00 annually. Each member receives a series of bulletins which give authoritative information about the whole subject of epilepsy, and a portion of the dues are used in carrying on research work in this field. Among physicians the "American League Against Epilepsy" (to which any interested and qualified physician may belong) is a chapter of the international organization. In epilepsy there would seem to be unusual opportunity and need for medical investigators, medical practitioners, patients, and the general public to unite in trying to solve a problem which is a puzzle and a pain to all.

THE DEVELOPING EGG AS A CULTURE MEDIUM*

ERNEST W. GOODPASTURE, M.D., NASHVILLE, TENN.

THIS paper deals with the chick embryo and its membranes as an individual living experimental host for a variety of infectious agents rather than as the source of viable cells and juices for tissue cultures.¹ The developing egg has proved to be susceptible to a greater number of viruses than any other living host, and it has also been found to be infectable by certain protozoa, spirochetes, fungi, bacteria, and rickettsiae.² To many of these infectious agents the hatched chick possesses an apparently complete natural resistance. The chick embryo, therefore, has a very high degree of susceptibility inherent in its cells and its developmental environment; it seems to have little or no capacity to acquire specific immunity before hatching.

The chick embryo is exceptionally useful for the study of many problems of infection of widely different kinds, and of resistance—natural, acquired, and passively transferred. Because of the large number and variety of infectious agents that can be cultivated in a pure state in the chick embryo, it is also a useful medium for the production in quantity of uncontaminated vaccines.

It has also been found that certain viruses can be modified by successive infections in embryos in such a way that they become less virulent for other hosts, so that in the modified form they can be used as infectious vaccines. Some viruses multiply enormously in the infected embryo in fully virulent form; this fact has facilitated the production of certain vaccines that can be used after inactivation.

Historically the first published account of experimental infection of the chick embryo of which I am aware was Levaditi's report, published in 1906, describing his results with the spirillum of fowls discovered by Marchoux and Salimbeni.³ Levaditi acknowledged his indebtedness for the technique to Borrel who infected embryos the year before with this microorganism but did not publish his observations.

Levaditi's experiments were of particular significance in that they suggested a relationship between the life processes of the embryo and the susceptibility to spirillosis. They emphasized also the phenomenon of the passive transfer of immune bodies through the egg from the mother to the offspring.

Rous and Murphy⁴ published in 1911 their results of implanting and inoculating chick embryos with a transmissible sarcoma of fowls and its filtrate. These experiments had important bearing upon virus infections and tumor culture, and upon matters relating to organic differentiation as they might affect susceptibility and immunity.

In 1920 Juan and Staub⁵ infected chick embryos with the virus of avian pest, and in 1929 Gay and Thompson⁶ obtained evidence indicating the propaga-

*From the Department of Pathology, Vanderbilt University Medical School, Nashville.

tion of vaccinia virus in these animals. Woodruff and Goodpasture,⁷ and Woodruff, Goodpasture, and Buddingh,⁸ demonstrated in 1931 the susceptibility of the chorio-allantois of chick embryos to the viruses of fowl pox, herpes simplex, and vaccinia. Their investigations called attention to the unusual susceptibility of chick embryonic tissues to viruses and to the possibilities inherent in the method for the study of a variety of infectious agents. Subsequently, Goodpasture and Anderson,⁹ Gallavan and Goodpasture,¹⁰ and Buddingh and Polk¹¹ demonstrated clearly the usefulness of the chick embryo for studies of the pathogenesis of bacterial infections, including those of *Hemophilus pertussis*, *Hemophilus influenzae*, and *Neisseria meningitidis*, for which there is no readily available host other than man.

Following these studies the chick embryo has been used extensively and the method has become recognized as a useful procedure for the investigation of virus infections and those infections due to a variety of parasites.^{9, 12}

METHOD

It is necessary to have a constant source of fertile eggs. The poultry industry has made available excellent types of incubators which are relatively inexpensive. The best ones are electrically operated and are provided with automatic control of heat and moisture and a simple device for daily rotation of the eggs.

As a rule, the younger the embryos the worse they stand operative procedures. For this reason, we prefer to use, wherever possible, embryos that have incubated for ten to fourteen days. The normal incubation period for hen eggs is twenty-one days; consequently, several days are available for experimental observations.

Opening the eggs, at first a tedious procedure, has been made simple, rapid, and uniform by the use of a cutting carborundum disk, rotated by means of a dental motor with attached flexible shaft and chuck. This machine is operated by means of a foot treadle which permits variable speed. Underlying the egg shell is a tough, fibrous membrane, called the shell membrane, which is a secretion product of the isthmus of the hen's uterus. When cutting a window in the shell for the purpose of inoculation or observation, the calcinated shell alone is first penetrated by means of the carborundum disk. The area outlined by the cut is then covered with a thin coat of hot melted paraffin to fix loose particles and to prevent contamination during succeeding operations. Next, the fibrous membrane is penetrated with a spear point needle and cut along the shell incision, leaving one side of the cap for a hinge or, if the cap is to be discarded, that side is easily torn across by pulling away the shell cap.¹³

Only eggs that have been proved to contain living embryos are operated upon. Fertility is determined by candling the egg; by this means the extent of development of the chorio-allantoic membrane may be seen, and its large blood vessels located if it is desired to expose them for purposes of injection or otherwise.

Beneath the fibrous membrane, upon which the calcium is deposited with its coating of mucons, lies the chorio-allantois, by means of which respiration takes place; on its outer surface is a layer of ectodermal epithelial cells inter-

rupted by abundant capillaries which underlie the epithelial layer and protrude through it. Beneath the epithelium, and supporting the blood vessels, is the fibrous tissue of the mesoderm, and below this is a continuous layer of endodermal epithelium. The chorio-allantois membrane is a very useful site to inoculate for many purposes; it can be viewed and manipulated easily and at will. The window, after inoculation or other operations, may be sealed by surrounding it with a layer of vaseline-paraffin mixture upon which is placed a cover glass. Through this cover glass one can see at any time what is going on superficially, and the membrane can be viewed through a dissecting microscope or, for higher magnification, through an Ultropaque equipment. If moisture collects beneath the glass, it can be readily removed by applying a blunt hot instrument to the glass cover.

Through the shell opening inoculations can be made into different parts of the embryo itself, into the amnion, or intravenously. Also, material can be removed at will for examination or culture. After the egg is inoculated, it is placed in an ordinary bacteriologic incubator on a wire tray with a diamond-shaped wire mesh of a size satisfactory to hold it in position with the window uppermost. The incubator temperature is maintained at about 37° C. For some purposes lower temperatures are advisable. For example, Bengtson and Dyer¹⁴ found that the rickettsiae of Rocky Mountain spotted fever were more numerous in inoculated eggs incubated at 33° C.

VIRUS INFECTIONS

The cells of the chick embryo have been found to be susceptible to infection by a much greater number of viruses than any other single host. Consequently, the embryo may be used as a convenient living medium for the cultivation and experimental investigation of a great variety of these agents.^{15, 16}

The following viruses that are pathogenic for man have already been cultivated in this medium, namely, those of smallpox, alastrim, and vaccinia; herpes simplex, virus B, yellow fever, and Rift Valley fever; St. Louis encephalitis, lymphocytic choriomeningitis, equine encephalomyelitis, louping ill of sheep, and rabies¹⁷; the common cold, epidemic influenza, and psittacosis.

Of viruses affecting animals, but to which man is apparently insusceptible, the following have been cultivated in chick embryos: Rous sarcoma, fowl pox, fowl plague, infectious laryngotracheitis of fowls, New Castle disease, infectious bronchitis of chickens, Pacheco's parrot disease, vesicular stomatitis of horses, myxomatosis of rabbits, ectromelia of mice, sheep pox, and pseudorabies.

Thus far among viruses affecting man, the following have resisted cultivation in the chick embryo, namely, those of molluscum contagiosum, warts, mumps, herpes zoster, varicella, poliomyelitis, and measles.

It has been reported that the virus of measles, for which there is no other adequately proved susceptible host than man, has been cultivated in the chick embryo, but there is as yet no acceptable confirmation.¹⁸

Most of the reports of virus infections have concerned only lesions as manifested in the chorio-allantois, little or no attention having been devoted either to distribution of virus in the embryo proper or to evidences of localization in

the body of the embryo as manifested by specific lesions. Frequently there has been no cytologic description of the membranal lesions themselves. Various routes of inoculating the embryo are accessible, and infection of the embryo proper, directly or by extension, offers great possibilities as yet too little realized. Classical examples of this potentiality are illustrated by the studies of vaccinia by Buddingh¹⁹ and of herpes simplex by Anderson.²⁰

It is to be emphasized that an adequate study of a virus infection, and for that matter any other sort of infection, should be founded upon a cytologic and histologic basis; and if one is to derive the most from the chick embryo method, morphology must direct investigations of pathogenesis. It is well known that most viruses induce characteristic changes in the cells they affect, and one can determine the course, distribution, and the fact of localized infections so well in no other way as by microscopic study of the cellular structure of the host.

RICKETTSIAL INFECTION

The rickettsiae of Mexican and European typhus fever have been cultivated in the chorio-allantois of chick embryos by Zia,²¹ and those of Rocky Mountain spotted fever by Bengston and Dyer.¹⁴ Cox has succeeded in growing the rickettsiae of Rocky Mountain spotted fever and of the typhus group in the yolk sac of the developing egg.²²

Inoculation of the chorio-allantois results in infection of the ectodermal epithelial cells, and it seems likely that growth in the yolk sac is the result of infection of the endodermal lining cells. No adequate study has been made of infection of the embryo proper by various routes of inoculation.

BACTERIAL INFECTION

The usefulness of the chick embryo method for the study of bacterial infection was indicated by Goodpasture and Anderson, who induced infections with pure cultures of *Staph. aureus*, *Strep. hemolyticus*, *Strep. viridans*, *B. aerogenes*, *E. typhi*, *B. abortus*, and *C. diphtheriae*. These authors called attention to intracellular growth of some of these strains and pointed out the importance of this phenomenon in the processes of invasion.⁹ Internal lesions of the embryo following membranal infection were described in some instances.

Subsequently, Gallavan,²³ and Gallavan and Goodpasture,¹⁰ described infection of the embryo with *H. influenzae* and *H. pertussis*. Localization of infection with the former microorganism in the brain and meninges and on the ciliated border of respiratory epithelium with the latter was described, and the similarity of these lesions to those encountered in human infections with the same bacteria was emphasized. Buddingh and Polk were able to infect embryos with the meningococcus, and under suitable conditions they reproduced, not only the septicemic form of disease, but also a specific suppurative meningitis.¹¹ Their results indicated that meningitis results from a localization of blood-borne meningococci.

Morrow and Berry²⁴ infected the chorio-allantois with *N. gonorrhoeae* and used this technique to study the effect of sulfanilamide therapy. This work was confirmed as regards infection by Hill and Pitts.²⁵

Other reports of bacterial infection of various kinds have been made by Pandit, Rao, and Shortt²⁶; Castil and Bloch²⁷; Mettzer, Beaudette, and Stokes²⁸; and Weil and Valentine.²⁹

SPIROCHETAL INFECTION

Morrow, Syverton, Stiles, and Berry³⁰ reported growth of *L. icterohaemorrhagiae* in the chick embryo, and this was confirmed by Davis.³¹ Chabaud³² and Oag³³ succeeded in infecting the embryo with *S. duttoni*. As yet there is no satisfactory evidence that *S. pallida* has been cultivated in this medium.

FUNGUS INFECTIONS

Goodpasture³⁴ suggested that the chick embryo method might be useful for study of fungus infections after observing the effect of certain contaminants on the chorio-allantois. Recently Moore³⁵ has called attention to the usefulness of the chick embryo for the study of a number of pathogenic fungi.

PROTOZOAL INFECTION

Levine, Brandly, and Graham³⁶ have infected chick embryos with *Tritrichomonas foetus* and Chabaud has used these embryos for studies of infection by certain pathogenic trypanosomes.³⁷

This incomplete list of publications will serve to indicate the usefulness of the chick embryo method for studies of a wide variety of infectious agents. Goodpasture, Douglas, and Anderson³⁸ have demonstrated the possibility of studying infection more indirectly by inoculating iso- and hetero-grafts of skin from susceptible animals, and Polk, Buddingh, and Goodpasture,³⁹ and Goodpasture and Anderson,⁴⁰ among others, have illustrated possibilities of the method for studies of immunity.

FUTURE POSSIBILITIES

The chick embryo is a living host that is susceptible to infection by a wide variety of pathogenic agents, and the possibilities of its use for study of pathogenesis are almost unlimited. Because of the practicability of introducing effective amounts of antiserum into the embryo, and because this immature animal apparently is incapable of producing antibodies in demonstrable quantity itself, an opportunity is afforded for studies of passive immunization.

Although the use of the chick embryo technique for investigation of chemotherapeutic agents of various kinds has only begun, it seems evident that it will afford an exceptionally good opportunity for chemotherapeutic experimentation.

The usefulness of the method for the production of certain vaccines in quantity for administration either as infectious or as noninfectious antigens has already been demonstrated, and it would seem likely that its adaptability to this purpose will be greatly extended in the future.

Buddingh and I¹³ in recent years have developed a satisfactory method for preparing antismallpox vaccine in quantity, free of bacteria, by infecting the chorio-allantois of chick embryos. Modifications of this method have been used by others for the same purpose and with satisfactory results. Our own experience has led us to believe that a vaccine thus prepared could with ad-

vantage supplant calf lymph for human antismallpox prophylaxis. A recent extensive report by Stevenson and Butler⁴¹ from the National Lymph Establishment is very favorable to its use. The method described by Buddingh⁴² of preserving vaccine in sterile serum, not possible with contaminated lymph of the calf, greatly prolongs its activity even against the adverse effects of body temperature.

Assuming a role of immense importance in individual and mass protection against yellow fever, endemic on two continents, are the recently developed methods of vaccination by the use of attenuated strains of yellow fever virus. The strain used by the International Health Division of the Rockefeller Foundation, with which over a million persons have been vaccinated in South America, is propagated routinely in tissue cultures, but for vaccine production it is inoculated into chick embryos. The infected embryos yield an abundance of virus. The vaccine induces a mild infection, without significant clinical symptoms, followed by the appearance of antiviral antibodies in the circulating blood signifying protective immunity.

Among the newcomers of viruses discovered to be pathogenic for man is that of equine encephalomyelitis, now thought to be an endemic infection among a variety of birds rather than a natural disease of horses. There are two immunologically distinct strains of this virus in our country, namely, the Eastern and the Western strains, and during the past year fatal infection with each has occurred in human beings. Both are highly infectious for chick embryos.

Beard and his co-workers⁴³ have described a vaccine prepared from virus cultivated in the chick embryo and treated with formalin that is being widely used with apparent success in animal prophylaxis. It is to be hoped that human infection with this virus will not reach proportions requiring similar immunizing procedures.

Beaudette⁴⁵ states that the New Jersey College of Agriculture supervises the production of laryngotracheitis vaccine at the Vineland Poultry Laboratories to insure purity and potency of the product. This virus is grown on the chorio-allantois with excellent results. These laboratories also produce their pigeon and fowlpox vaccine in the same way, i.e., by cultivation in the chick embryos.

Several publications have demonstrated the usefulness of the chick embryo method for inducing variation of certain viruses in the direction of lessened virulence thereby affording the possibility of experimental development of strains suitable for prophylactic vaccination. Thus far this has been accomplished, as indicated by the reports of Burnet⁴⁴ with the virus of influenza; of Beaudette⁴⁵ with the virus of bronchitis of fowls; of Penna and Mousatche⁴⁶ with the virus of yellow fever; of Buddingh⁴⁷ with the virus of fowlpox; of Anderson²⁰ with the virus of herpes simplex; and recently, of Dawson⁴⁸ with the virus of rabies. The possibility of future developments along this line for modifying not only viruses but also other types of pathogenic agents would seem to be particularly promising.

Finally, there remains the probability that the chick embryo will eventually prove to be the means of cultivation of certain viruses that so far have resisted transmission to species other than those in which they occur naturally.

There are already indications that the virus of measles will infect chick embryos,¹⁸ and if this is confirmed, an opportunity might be afforded to produce an effective vaccine for human prophylaxis.

Possibly fruitful lines for investigation in relation to infection could be initiated by means of the chick embryo technique in the direction of attempts to influence susceptibility and resistance by experimental variation in vitamin content and hormonal balance. The problem of the nature of natural resistance can also be attacked, because in many instances the highly susceptible cells and tissues of the embryo become completely insusceptible with advancing maturity.

The potentialities of the chick embryo method for studies of infection have only begun to be recognized, and one may look forward hopefully to a much greater realization of its usefulness in the future.

THE VIRUSES*

MALCOLM H. SOULE, Sc.D., LL.D., ANN ARBOR, MICH.

AS WE proceed down the scale of plant and animal life, from the largest to the smallest forms, no marked difficulties in differentiation are encountered until dimensions of 0.1 to 0.2 mm. are reached. At this level the hyphae of some of the molds and the itch mite are still clearly discernible to those with good vision. The wiggling extremities of the latter leave no doubt in the minds of the afflicted regarding classification. Continuing, one then enters the realm of the microcosm where with other types the yeasts and protozoa are unicellular representatives of the two great kingdoms. Near the lower border of the microscopie world stand the pleuropneumonia organisms, the Rickettsia and certain inclusion bodies associated with virus diseases, the morphology and structure of which are not too clearly revealed by the best staining methods. Are these forms plants or animals? Do the limits of microscopic vision coincide with an abrupt and exact transition point between the living and the non-living? The fundamental methods and techniques for the investigation of this problem have been mere extensions and refinements of the procedure employed with the bacteria; hence, progress to a marked degree has paralleled developments in this field.

The early acceptance of bacteria as agents of disease was based on the regularity with which they were present in the tissues, their growth on artificial media, and the infectivity of the cultures for susceptible animals. Detection, because of size, depended upon the microscope. The capabilities of this instrument were held to be entirely adequate to reveal all living things. Pasteur was the first to question this belief. In 1884 he found that the spinal cord of dogs which died of spontaneous rabies contained no visible microbes and gave no cultures in vitro, but embodied elements which multiplied when introduced subdurally into normal dogs or rabbits. With his usual genius and imagination Pasteur postulated the existence of a living submicroscopic world containing the same wealth of members as made up the microcosm. On this basis, the newly discovered rabies virus was the first representative. Thereupon, the term virus connoted a viable microscopically invisible agent rather than a poison. This interpretation of the word was promptly accepted, due in no small measure to the support of Pasteur and of additional outstanding discoveries.

The next development was in 1892 when, according to Iwanowski, the juices of plants with mosaic disease remained infectious after passage through the recently developed Chamberland filters of unglazed porcelain impervious to bacteria. Beijerinck confirmed and extended this observation, and in 1897 the infectious agent of hoof and mouth disease was recognized in what appeared

*From the Hygienic Laboratory, University of Michigan School of Medicine, Ann Arbor.

to be sterile filtrates of diseased tissue. The designation, *virus*, now acquired additional meaning because of the filtration experiments, and it was applied for a long period of time only to those disease-producing entities, so-called filtrable viruses, capable of passing filters that retained ordinary bacteria. The agents of mosaic disease of plants, hoof and mouth disease, and on discovery, canine distemper, equine encephalomyelitis, lymphopathia venereum, poliomyelitis, influenza, yellow fever, and others, came under this category. In most instances, before the virus etiology of a disease could be established, it was necessary to account for and to eliminate the claims of certain visible organisms, either bacteria or protozoa, to this role. By way of example, there were the *B. cholerae* suis in hog cholera, *Bacillus X*, *B. icteroides*, and *Leptospira icteroides* in yellow fever, and more recently, greening streptococci in influenza and poliomyelitis.

During the past decade, following a renewed interest in viruses, and, as an outgrowth of intensive studies of their chemical and physical properties, the definition has been further narrowed with emphasis not only on their ability to traverse fine membranes, but also on the intimate relationship which seems to exist between virus and host cell, such as their intracellular position and their failure to grow in the absence of living cells. The viruses form a continuous series, ranging in size from within the lower limits of ordinary microscopic vision (vaccinia 250 $m\mu$) to dimensions of 10 $m\mu$ (hoof and mouth virus). In this submicrocosm, problems of classification and questions such as whether certain species are plants or animals assume only academic significance, they, the viruses, are unequivocally entitled to the designation, protists or first forms. The smallest viruses are theoretically beyond the range of the recently introduced electron microscope, and instruments employing shorter wave lengths or some other principle will have to be developed before we can make direct observations of the morphology of these agents which approach molecular dimensions. The available data have been ascertained by selective filtration, using graded collodion filters, and have been confirmed and extended by ultracentrifugation. In keeping with variation in the size of the cells of any one bacterial species, the viruses differ in size within quite definite limits.

Viruses were first recognized and described in terms of biological activity; they continue to be revealed only by means of this attribute. One of the most fruitful fields for the obtaining of fundamental information in virus research is with the plant pathogens of which there are many. The restrictions, such as excessive costs for the purchase and care of animals, elaborate quarters, and possibilities of human infection which confront those studying the animal viruses, are nonexistent. Here, one may have on hand at any one time thousands of infected plants in modest surroundings, and with no danger to those associated with the investigation. A few of the intriguing problems of viruses and virus infections, the unraveling of which at present seemingly offers insurmountable obstacles, will now be considered.

Viruses multiply only within certain living cells, thus their purposeful cultivation in vitro is limited to those media containing living tissue. Sedulous attempts to grow viruses in the absence of viable cells have failed, yet the belief that viruses are living agents depends upon the fact that they are capable of re-

production and adaptation in the living plant or animal body. When an animal, chick embryo, or tissue culture, such as the agar roll tube, is inoculated with a definite quantity of the virus, it is found, after a suitable incubation period, that the virus has reproduced itself in relatively enormous quantities, a small fragment of tissue yielding millions of infective doses. Perpetuation of the virus and its proliferation can be carried forward at will for unnumbered generations or passages. But why this intimate relationship between parasite and host cell? Two theories may give some insight into the phenomenon: (1) Is it a protective mechanism from toxic substances in the extracellular spaces? or (2) May we assume that a virus is an organism which by persistent localization within the cell is deficient in enzyme systems and has thus lost the power to synthesize its own nutrient materials to the state at which they are active within the cell; and they, therefore, cannot grow in extracts of the cell but only within the cell itself? If we follow this latter theory to its logical conclusion, we may deduce the nonviable nature of viruses, which attitude at present is decidedly popular and is gaining in favor. It is necessary merely to postulate that in this adaptation to an intracellular existence the enzymes have been progressively lost and appropriated from the cell. Ultimately a mere nucleoprotein is left which is itself inert and only exhibits the characters of life, borrowing and directing the enzyme system from the cell it invades for its own reproduction. Such an implication is in keeping with the work of Stanley, who has isolated the virus of tobacco mosaic, as well as certain other viruses, as crystalline nucleoproteins with definite chemical and physical properties. Nevertheless, it should follow that if this process is essentially progressive, viruses should exist which have not yet lost their power of synthesis to such an extent that an intracellular existence is mandatory. The ubiquitous distribution of saprophytic viruses is predicated by certain British workers who have actually isolated several species from sewage and grown them in cell free media. If we adopt the first theory, which accepts viruses as living entities, the attainment of the goal of the *in vitro* cultivation resolves itself into one of two possible plans: (1) the development of techniques for the neutralization or removal of toxic substances, or (2) the accurate reproduction within the culture tube of the nutritive conditions within the cell, thus permitting the virus to grow in a sterile medium devoid of cells. The second concept becomes a straightforward problem of analytical and synthetic organic chemistry, but is tinged by the evidence from epidemiologic observations that a belief in the spontaneous fabrication of viruses by host cells is unwarranted.

Many virus-infected cells contain inclusion bodies appearing in the cell cytoplasm or nucleus, or in both cytoplasm and nucleus. On rare occasions the inclusion bodies characteristic of two different virus diseases may be present simultaneously in the same cell, thus evidence of a double infection. The inclusion bodies are pleomorphic, of various kinds and peculiar to certain types of cells. Negri bodies discernible within the ganglion cells of the brains of animals affected with spontaneously occurring rabies, and Guarnieri bodies within the epidermal cells in lesions of vaccinia are among the best known

examples. They stain readily and are easily recognizable in clinical material, yet the nature, significance, and relationship of these and other inclusion bodies to the specific virus with which they are associated are not clear.

In diagnostic procedures the presence or absence of inclusion bodies is of considerable importance. Unfortunately, their distribution is limited to a relatively small proportion of the virus diseases. Are the inclusion bodies and the virus one and the same, the former aggregates of the latter? Are the inclusion bodies degenerate products of cells attacked by virus, or are they virus clothed with cellular material? There are sponsors for each of the three theories. Preparations of pure inclusion bodies, the elementary bodies of vaccinia, have been obtained and subjected to biological studies. It appears from the results that the elementary body is a viable organism deficient in certain enzymes.

The viruses, like bacteria, manifest a striking selective affinity for particular tissues in the bodies of their host, as for example, the neurotropic viruses of rabies, lethargic encephalitis, poliomyelitis, and equine encephalomyelitis, and dermatropic herpes virus. The viruses in these diseases presumably proliferate only in the tissues attacked according to their selective affinities. A number of virus diseases occur as acute, generalized infections, notably among which are hog cholera, distemper, and influenza. In these the causative viruses multiply in the circulating blood and viscera and, as might be expected, are concentrated in these locations.

A striking feature of many of the viruses, which is not highly developed among bacteria, is their adaptation to foreign hosts and individual tissues. Such virus agents as poliomyelitis can be ultimately perpetuated in certain species of monkeys, and vaccinia, yellow fever, and herpes, which are not neurotropic in natural infections, may be adapted to the nervous system of laboratory animals by experimental procedures. Considerable difficulty may be encountered in making the initial transfer from the natural to the experimental host. The first "take" may cause little disturbance or escape observation. This is particularly true in infantile paralysis. The infection in monkeys following inoculation with human material is often detected only after prolonged fatigue by vigorous exercise. The recent report of the production of poliomyelitis in the cotton rat (*Sigmodon hispidus hispidus*) following inoculation with monkey passage material at present seems to be limited to only one strain of human virus. In general, many passages are required for the attainment of fixed virulence and type. With the virus of yellow fever the phenomenon of changing this typical viscerotropic into a fixed neurotropic virus occurs as a result of intracranial inoculations in white mice.

Of added interest is the fact that a given virus, when repeatedly passed serially through a particular species of animal, may increase in virulence for this species and progressively lose its virulence for the original host. The classical example of this change is the rabies virus which when maintained in rabbits becomes highly infectious for these animals but appears to diminish in infectiousness for dogs. Accidental infections in human beings with monkey

strains of the virus of poliomyelitis, as well as rabbit brain rabies vaccine, preclude any generalizations at this time.

Certain findings with other diseases are of considerable interest. Watson, experimenting with the virus of equine encephalomyelitis, succeeded after several failures in establishing the malady in guinea pigs by intracranial inoculations of naturally infected horse brain. Following a few passages it attained high virulence and seemed stabilized as a neurotropic virus for guinea pigs. By similar procedure the guinea pig strain was established and fixed in white mice and, in turn, the mouse strain in the chick embryo. The comparative infectivity and virulence of the three strains so developed in the guinea pig, mouse, and chick embryo, respectively, were significant. When the virus-containing tissues of these animals were titrated in dilutions carried to 1:100,000,000, using 0.1 cc of each dilution as a volumetric dose for inoculation, the minimal infective dose of the guinea pig virus was represented as 1:1,000, the mouse virus as 1:100,000 and the chick virus as 1:100,000,000. That is to say, the guinea pig virus had 50 to 100 times greater concentration and infectivity than the horse virus, the mouse virus 100 times that of the guinea pig virus, and the chick virus 1,000 times that of the mouse virus.

Animals which have recovered from a virus disease or which have survived experimental infection with a virus of modified or attenuated activity exhibit a certain immunity to a subsequent infection with the same virus. The usual antibody responses common to bacteria, such as agglutinins, precipitins, and neutralizing antibodies, are likewise elicited by viruses. In some virus disease the immunity may be of long duration, whereas in other cases the immunity may be relatively short-lived. We have on the one hand smallpox in which immunity usually persists throughout life, and in contrast such virus disease as herpes simplex where frequent recurrence at the site of the preceding lesion is almost the rule. In many instances in which immunity for life seems apparent such as poliomyelitis and measles, the initial resistance may be constantly reinforced by successive exposures; in some virus diseases immunity may be the result of the omnipresence of a definite but limited number of cells infected with the virus. Workers in Dutch Guiana have repeatedly called attention to the solid immunity of the Bush Negroes to malaria and the regularity with which protozoa are distributed in their blood; the so-called "premunition" of the French workers. A similar situation exists in infectious equine anemia of horses, a highly infective but noncontagious disease. The virus is present and apparently multiplies in the circulating blood and has no known special affinity for cellular tissues. The minutest quantity of blood will transmit infection and disease to a healthy horse.

Horses which recover from the disease, and there are many, are apparently immune from further attack but may carry the virus in their blood for the rest of their natural lives and thus become virus reservoirs. As an instance, the blood of a horse which had recovered from the spontaneously appearing disease when about 5 years old, proved highly infective for horses at frequent intervals over a period of fifteen years. Probably one of the most important factors in the epidemiology of virus diseases may be the convalescent carrier.

The artificial stimulation of active earned immunity to virus diseases is dependent seemingly on the development of methods for the production of the virus agents in larger quantities and in a more easily manipulated form. The tissue culture preparations are extremely promising in this direction. On the other hand, passive immunity against virus diseases has made very little progress. The administration to children who have been exposed to measles of convalescent serum or the serum of adults who at one time had measles has imparted protection. But with the neurotropic viruses, such as poliomyelitis, the clinical use of normal adult serum or convalescent serum is of decidedly questionable value, yet *in vitro* such products have exhibited specific neutralizing power. The intracellular position of viruses once they are established, and the lack of penetration by antibodies, are without doubt the mechanism by which the usual beneficial effects of antisera are denied the host.

The portal of entry, the avenue of elimination, and the source of the infection are outstanding unsolved enigmas in connection with many of the virus diseases. Often transmission is by recognized routes, such as the bite of a rabid dog, the bite of an infected mosquito, and the inhalation of infected droplets or spray; unfortunately, in many instances, such information is woefully lacking. One has but to consider poliomyelitis to be impressed with the confusion; there is no consensus of opinion regarding the route by which the virus enters the body of the susceptible host. In addition, an explanation for such a phenomenon as the sporadic appearance of an isolated case of poliomyelitis in a white child in India without seeming contact with any other patient with the disease, which rarely if ever occurs among the natives, worries the epidemiologist.

Perhaps the most intriguing field to those interested in virus research is the possible association of these agents with neoplasms. The evidence seems unequivocal relative to the carcinogenic action of the Shope papilloma virus of rabbits, but the demonstration of a similar etiology in human malignancies is a challenge to the student of virus research.

FUNGI AND FUNGOUS DISEASES*

FREDERICK W. SHAW, M.D., AND J. DOUGLAS REID, Sc.D.
RICHMOND, VA.

THE majority of fungous infections with which the clinician comes in contact are those which produce superficial lesions of the skin. They are caused for the most part by members of the genera *Achorion*, *Microsporum*, *Trichophyton*, and *Epidermophyton*. The widespread infection in this country with these dermatomyces and the consequent familiarity with their clinical manifestations have made the physician aware of their fungous nature. Diagnosis of the etiologic agent can usually be made by direct microscopic examination of scrapings from the lesions. Occasionally this procedure is insufficient for identification. A case in point is the differentiation of *Microsporum audouinii* and *Microsporum lanosum*, both of which produce similar structures in the tissues, but differ culturally. Clinical differentiation is based on the more inflammatory type of lesion produced by *Microsporum lanosum*, but it has been shown by Dowding and Orr¹ that noninflammatory reactions of the tissues with this parasite are not uncommon. In such cases identification of species is necessary before correct therapeutic procedures can be instituted. *Microsporum lanosum* infections respond readily to local treatment with ointments and the like, whereas those due to *Microsporum audouinii* can be treated successfully only after epilation.

Less readily recognized are those mycotic diseases which either occur less frequently or produce systemic infection without an initial local lesion that might give a clue to the nature of the causative organism. A study of the literature reveals the fact that diagnosis in such infections is often delayed considerably, or in the case of a fatal outcome, determined only at autopsy. With the desire to aid the physician and the laboratory worker in the early recognition and identification of the organisms of these obscure mycotic infections, we are presenting a review of the outstanding features of several of them, together with some of our own experimental findings.

CHROMOBLASTOMYCOSIS

The appearance of the lesions in dermatitis verrucosa (chromoblastomycosis) is simulated by several infections caused by different etiologic agents. Clinically it may be confused with tuberculosis cutis, blastomycosis, and at times with Madura foot and coccidioidal granuloma.

The first case of dermatitis verrucosa from which a black fungus, *Phialophora verrucosa*, was isolated was reported by Lane² in 1915. According to Emmons and Carrion,³ Pedrosa in South America had isolated a similar fungus from a case of verrucous dermatitis in 1911, but the case report was not pub-

*From the Department of Bacteriology and Parasitology, Medical College of Virginia.

lished until 1920. Since these initial reports were made, a number of other cases have been added to the literature, the majority having been found in South America and Puerto Rico where the disease is apparently more common than in this country. Few cases have been reported from the United States. But like other types of fungous infections which are little known in this country, several of which are mentioned in this paper, their rarity may well be due to failure to recognize their fungous nature.

Fig. 1.—*Hormodendrum pedrosoi* in tissue section from a case of chromoblastomycosis of forearm. ($\times 750$.)

The lesions of chromoblastomycosis occur most frequently on exposed surfaces of the body, particularly on the feet. Occasionally other parts of the body may be attacked. Single cases have been reported where the primary infection occurred on the buttocks (Lane²), and on the hand (Carrion,⁴ Martin and associates⁵). Infection may begin as a small, itchy, vesicular skin eruption which gradually extends to produce variously sized areas of infection in adjacent tissues. Wartlike, dull red or violaceous nodules form. These nodules slowly increase in size, forming papillomatous lesions which may become ulcerated. The disease follows a chronic course and does not appear to have the tendency possessed by *Blastomyces dermatitidis* (Gilehrst and Stokes, 1898) to invade other organs of the body.

The term chromoblastomycosis was coined by South American workers to describe the appearance of the organism as seen in tissue preparations. Through common usage this name has gained general acceptance, although the causative agent is not a blastomycete. Differential diagnosis can be made by microscopic examination of scrapings from the lesions which are mounted in sodium hydroxide. The organisms appear as rather large, double-walled, brown, spherical cells. Transverse septa are noted at times. They are distinguished microscopically from *Blastomyces dermatitidis* by their dark color and absence of budding forms and from *Coccidioides immitis* by the absence of endospore formation. Growth takes place slowly when suitable material is transferred to Sabouraud's dextrose agar. Culturally they appear as black colonies with short aerial hyphae, in contrast to the white growth produced initially by *Blastomyces dermatitidis* and *Coccidioides immitis*.

The three species of fungi which have been isolated from the lesions of chromoblastomycosis are *Phialophora verrucosa* (Thaxter, 1915), *Hormodendrum pedrosoi* (Brumpt, 1922), and *Hormodendrum compactum* (Carrion, 1935). Differentiation has been based on the size, shape, and mode of production of the spores in cultures. In the tissues, however, the cells of all three species have a similar appearance. Clinically the lesions produced by *Hormodendrum compactum* differ from those usually seen in chromoblastomycosis only in the absence of the nodule formation.⁴ This species distinction is of interest mainly to the mycologist.

The disease, once having become extensive, is generally considered incurable, but the slowly progressive nature of the infection should allow opportunity for experimental work in the therapeutic field. Moderately successful results have been obtained by Carrion and Koppisch⁶ who noted extensive healed areas and a reduction in the size of the nodules after intravenous treatment with large doses of sodium iodide. Martin and co-workers⁵ reported general clinical improvement of the skin lesions following daily iontophoresis treatment with copper sulfate for a period of five months. A marked reduction in the number of fungi in the lesions occurred. Oral administration of potassium iodide and autogenous vaccine therapy, which was also tried in this case, was considered of questionable value due to the small amounts given.

TORULA MENINGITIS

Central nervous system infection with a yeastlike organism, *Torula histolytica* (Stoddard and Cutler, 1916) was first reported by von Hansemann⁷ in 1905 from Germany. Since that time, additional cases with a wide geographic distribution have been observed, bringing to a total of sixty-four the number of reports now published. Particularly excellent reviews of many of these cases have been written by Freeman⁸ and Levin.⁹

The protean clinical manifestations of meningoencephalitis due to *Torula histolytica* have made the diagnosis of this disease a difficult one. This, and the apparent failure of the clinician to bear in mind the possibility of the invasion of the central nervous system with this organism, have frequently been responsible for such initial diagnoses as brain tumor, tuberculous meningitis, encephalitis, or cerebrospinal syphilis. Because of this, several writers have raised the question as to whether this infection may not be less rare than the number of cases would lead one to believe.

Obviously, in a disease which offers such a variety of clinical impressions, a definite picture cannot be given, but certain symptoms have been commonly reported. At the onset there is an intermittent, frontal headache, often increasing in severity. Weakness, dizziness, nausea, vomiting, and disturbances of vision are frequently noted. The patient is usually afebrile, or at most, a low-grade fever is present. Gradual loss of weight and strength are manifest during the course of the disease, the duration of which may vary from several weeks to a number of years before death occurs.

Ante-mortem diagnosis can be made only by examination of the spinal fluid. The cell count usually varies between 100 and 500, with a predominance of lymphocytes. Yeast cells may be seen at times in the unstained preparations, but more satisfactory examination of the spinal fluid can be made with Gram's

stained or India ink preparations. In the former, the yeast cells appear as gram-positive oval cells from 5 to 8 microns in diameter; budding forms may be seen occasionally. The India ink preparation offers the advantage of making the capsular material plainly visible. This capsule appears as a clear halo surrounding the thick cell wall and distinguishes the cells of *Torula histolytica* from those of the *Monilias* with which they might be confused. But the presence of a capsule is not alone sufficient proof of their pathologic significance. Further study of the organism should be made by culture and animal inoculation.

Fig. 2.—Budding cell of *Torula histolytica* in tissue section of mouse brain. ($\times 3200$.)

The centrifuged spinal fluid sediment should be streaked on Sabouraud's dextrose agar plates and incubated at either 37°C . or at room temperature. The initial growth occurs in from forty-eight to seventy-two hours as small, smooth, moist, cream-colored colonies which become tan or brown upon aging. The cells in the culture are variable in size, ranging from 2 to 10 microns in diameter, although larger cells may be seen. Budding cells are numerous. The capsules can be demonstrated in the cultural material by the India ink method. Large capsules are found most frequently in the more virulent strains.¹⁰ Sugars are usually not at all, or only feebly, fermented.

Mice and rats are the most susceptible of the laboratory animals to infection with *Torula histolytica*. Rabbits and guinea pigs are less so. Intraperitoneal inoculation of a heavy saline suspension of the culture into mice results in a generalized infection with constant involvement of the brain and meninges.¹¹ Death of the animal usually occurs in from six to eight days, but life may be prolonged for several weeks or months.¹² At autopsy encapsulated forms can best be demonstrated from the abdominal fluid and less readily so from the lungs, liver, spleen, and brain, although the organisms are numerous in these organs.

The route by which *Torula histolytica* first gains entrance into the human body is not known. The general opinion is that the respiratory system is the most likely point of initial invasion.

As yet there is no satisfactory treatment for the infection when it occurs in the central nervous system. Intravenous and oral administration of iodides has been tried without beneficial effect. All cases to date have been fatal.

SYSTEMIC HISTOPLASMOSIS

The first three cases of a new disease caused by the parasite, *Histoplasma capsulatum*, were reported by Darling¹³ from Panama between the years 1906 and 1908. Due to the appearance of the organism in the tissues obtained at autopsy, the disease was believed to be a protozoan one bearing a resemblance to kala-azar. Not until DeMonbreun¹⁴ in 1934 cultivated the parasite from autopsy material was the fungous nature of the disease discovered. Since Darling's initial reports, ten additional cases, all occurring in this country, have been added to the literature. Nine of these cases have been reported within the last six years, which may indicate that familiarity with the clinical symptoms has resulted in the recognition of cases that may have been missed previously.

The disease affects the reticulo-endothelial system, and it has been suggested by DeMonbreun¹⁴ that cytomyeosis of Darling rather than histoplasmosis of Darling would best describe the nature of the infection. However, the name histoplasmosis has priority and most cases have been reported under this terminology.

The onset is of an insidious nature, the chief complaint being weakness and loss of weight. Severe sweats, particularly at night, may occur. Splenomegaly, hepatomegaly, irregular fever, secondary anemia, leucopenia, and enlargement of the superficial lymph nodes are characteristic findings. In cases with the above-mentioned symptomatology, the possibility of infection with *Histoplasma capsulatum* should be considered.

Diagnosis can be made by finding the parasite within the cytoplasm of the large endothelial-type cells in blood smears or sternal bone marrow smears. When stained by Wright's method, they appear as bluish or bluish-red, oval cells, from 2 to 4 microns in diameter, surrounded by a clear capsular-like substance. The cytoplasm is characteristically situated along the side walls or at one end of the cells, but the absence of any body resembling a blepharoplast distinguishes this parasite from the Leishman-Donovan bodies found in kala-azar, with which it might be confused. Few or many of the parasites may be found within a single cell. Near the terminus of the infection they are phagocytosed by the polymorphonuclear cells also. The stage of the disease at which the parasites appear in the blood in sufficient number to be readily found is not known, since in only two cases (Dodd and Tompkins,¹⁵ and Reid and co-workers¹⁶) has antemortem diagnosis been made by blood smear examination. In each case the diagnosis was made late in the infection.

The organisms can be cultivated on such media as Sabouraud's dextrose agar, blood agar slants, or semisolid veal infusion blood agar. Possibly earlier diagnosis might be made by the culture of the blood because of the larger amounts that can be examined. We have had some indications that this may be true from animal experiments that have not yet been published. Two growth phases of the organism occur, depending upon the media used and the temperature at which the cultures are incubated. In semisolid media or on blood agar incubated at 37° C., a yeastlike form develops within from six to ten days and may be confused at first with other species of fungi, such as the *Saccharomyces* or *Torula*, as mycelia do not form readily under these growth conditions. A mycelial type of growth occurs when transplants of the yeast form are made

to Sabouraud's dextrose agar and incubated at room temperature. Small colonies, with aerial hyphae which give them a downy appearance, are visible, usually within a week. The gross appearance of the colony is not diagnostic and portions of it should be examined in wet mounts for the developing arthrospores. The older spores of *Histoplasma* and related species have rather typical tubercle-like processes which extend out on all sides of the cell wall giving them the appearance of "ancient Teutonic warelubs."¹⁴

Fig. 3.—Sternal bone marrow smear from a case of histoplasmosis, showing a reticuloendothelial cell containing numerous parasites within its cytoplasm. (Wright's stain, $\times 1000$.)

Determination of the pathogenic nature of the parasite can be made by injection of the yeastlike form into suitable experimental animals. Intraperitoneal inoculation into guinea pigs produces a chronic, afebrile, systemic disease with pathologic changes not unlike those found in man.¹⁵ The animals can be autopsied after the second week of infection. Stained smears or tissue sections of the spleen, liver, lungs, and bone marrow should be examined for the parasites which are similar in appearance to those found in the tissues of infected human beings. The fungus can also be cultivated from the tissues. Monkeys are also susceptible to infection, and puppies and mice less so.¹⁴ Rabbits have thus far proved refractory to infection.

As only two cases have been diagnosed during life, there is little that can be said as to the effectiveness of specific therapy. Symptomatic treatment with sodium bicarbonate and blood transfusions as reported by Dodd and Tompkins¹⁵ gave only temporary improvement. In the case recorded by Reid and his associates,¹⁶ oral administration of potassium iodide proved of no value. As the diagnosis in both of these cases was made after the parasite had invaded the body in massive numbers, little could be expected from the therapeutic measures that were tried. In a case reported by Clemens and Barnes,¹⁷ in which diagnosis was made at autopsy, sulfanilamide was given a brief trial, but the absence of clinical improvement caused them to discontinue this form of treatment. That the use of arsenicals might have a beneficial effect has been suggested by Shaffer, Shaul, and Mitchell.¹⁸ Their opinion is based on the results obtained with arsphenamine by Nègre and Bidre in the therapy of human epizootic lymphangitis. "Since some writers have maintained that there is

similarity between *Cryptococcus farciminosus*, the etiologic organism of epizootic lymphangitis, and the parasitic agent of histoplasmosis, one of the arsenicals might theoretically be indicated in treatment of the latter."

SUMMARY

The clinical symptoms and laboratory procedures of use in the diagnosis of several of the less commonly recognized mycotic infections, chromoblastomycosis, torula meningitis, and systemic histoplasmosis, are presented.

MEDICAL PROBLEMS OF HIGH ALTITUDE FLYING*

CAPT. HARRY G. ARMSTRONG, M.C., U.S. ARMY, AND J. W. HEIM, PH.D.
DAYTON, OHIO

HISTORICAL DEVELOPMENTS

IT IS interesting to note that while airplanes are of relatively recent origin, medical studies of high altitude flying are not. During one of the earliest balloon flights, on December 17, 1783, to be exact, the balloonist reported severe pains in his ears—the first of a long series of complaints which have during the intervening 157 years gradually led to the establishment of aviation medicine as a recognized specialty of medical science.

In 1862 Glaisher and Coxwell made a balloon ascent to an altitude of approximately 29,000 feet, during which the former noticed a series of strange symptoms marked by loss of visual acuity and hearing, paralysis of the legs and arms, and finally by unconsciousness. At the same time his companion Coxwell also found that his arms were paralyzed but had the presence of mind to seize the valve rope with his teeth and start the balloon downward. Glaisher's published accounts of this and other flights came to the attention of Paul Bert, a brilliant French physiologist, who began a study of the effect of decreased barometric pressures.

Three years later Bert¹ published his famous "*La pression barometrique.*" This work dealt with increased as well as with decreased atmospheric pressures, and the number and accuracy of his experiments and deductions considering the facilities with which he had to work are astounding. Bert was the first to prove that the principal effect of high altitude was due to the decreased partial pressure of oxygen; he carried out innumerable researches concerning carbon dioxide in the lungs and blood, and probed deeply into the question of respiration and blood gases under decreased barometric pressures. In addition, he observed many mechanical effects of barometric pressure changes.

Following the work of Bert there was little or no further work done in this field until about the last year of World War I. At the outbreak of that war the airplane was not well developed, and it was 1916 before its value as a war weapon was fully utilized. With the improved performance of the war planes came the problem of oxygen want at high altitude. While there were many in the different countries who studied this problem, their investigations were all overshadowed by the researches of E. C. Schneider, who worked in the Army Air Service, Medical Research Laboratory at Mineola, Long Island, from 1918 to 1920.

RECENT DEVELOPMENTS

Between 1920 and 1935 there were but few medical studies on high altitude flying. Since 1935, however, the amount accomplished has been tremendous.

*From the Aero Medical Research Laboratory, United States Army Air Corps, Wright Field, Dayton.

The stimulus that brought about this renewed medical research arose from several sources. The principal one of these was the marked climbing ability of our newer type airplanes and the desirability of operating at higher levels, which has certain marked advantages in both civil and military aviation. In civil aviation airplanes develop more speed on less power at altitude, and at the higher levels much of the stormy weather and bumpy air is avoided, contributing both to the comfort and to the safety of the flight. In military aviation the same considerations hold true. In addition altitude is an excellent means of concealment and protection from enemy aircraft and antiaircraft artillery fire.

The rate of climb and the altitude to which a commercial air liner may go are limited, however, not by the performance of the airplane but by federal regulations designed to protect the passenger. At the present time the allowable maximum altitude is 18,000 feet. Thus great care must be exercised during the discussion to follow to distinguish between the effects of high altitude flying on commercial passengers, limited by regulations as indicated above, and the effects on military pilots, limited only by the performance of the airplane or the tolerance of the human organism.

A second factor important in this connection is the number of persons who may be involved. As of January 1, 1940, there were 31,000 licensed civil pilots in this country, and about 20,000 more in training. By January 1, 1941, it is estimated that the number of licensed civil pilots will be increased to 50,000 and by July 1, 1943, to 100,000. In military aviation the number of pilots and combat crew members is approximately 10,000, which in the event of a national emergency would quickly be increased to well over 100,000. By far the largest number of fliers is composed of those commercial passengers carried by air. In the past twelve-month period this number amounted to approximately 3,500,000 persons, and represents an increase of 43 per cent over that of the year previous. At this rate of increase we may expect over 20,000,000 persons to be transported in scheduled and unscheduled air transport operations during the next five years.

CURRENT PROBLEMS

The current medical problems of high altitude flying depend principally on the altitude attained. As a consequence, the problems of commercial air transport operations are fewer and less serious than those in military aviation, since the former is limited to 18,000 feet. In either instance all the deleterious effects of altitude flying are brought about by the decrease in atmospheric temperature and pressure with ascent.

The temperature of the atmosphere decreases about 2° C. for each 1,000 feet of ascent until 35,000 feet has been reached. Above that altitude the temperature remains constant at -55° C.

In spite of winter-flying clothing, personnel begin to suffer at about -10° C. The hands and feet are the first parts affected, followed by the back, chest, abdomen, and legs in order. At first there are chilly sensations accompanied by increased metabolism and muscular restlessness. These chilly sensations change to discomfort, and the acuity of touch sensations and muscular reactions is dulled. As the cold increases, there is numbing of the parts, producing clumsiness of movements. The muscles assume a state of mild tonic contraction.

which further hampers and restricts free movement. Discomfort changes to pain and generalized shivering appears. Voluntary muscular movements become sluggish, and finally tissue destruction and death may occur at temperatures of -25° to -40° C.

Very recently Grow² has added a considerable amount of data to our knowledge of the effect of cold. His attention was first attracted to this problem when he observed that the mental state of persons suffering from exposure to cold was similar to that of those suffering from anoxia. By animal and human experiments he was able to show that such exposure produced lowering of the body temperature, slowing of the circulation and respiration, lowering of the oxygen content of the arterial blood (of animals), and tissue anoxemia of both animals and man. These findings are particularly significant in aviation due to the fact that anoxemia may also occur from decreased atmospheric pressure at high altitudes.

The solution to the problem of cold in high altitude flight is to close and heat the cabin. This has been satisfactorily accomplished in civil aircraft and to a certain extent in military aviation.

ANOXIA

During ascent the composition of the atmospheric air remains constant but its total pressure and partial pressure of its component gases decrease. This decrease in turn brings about a decrease in the alveolar oxygen tension and in the oxygen saturation of the arterial blood. This results in a tissue anoxia to which, in aviation, the term "altitude sickness" has been given.

Objective Symptoms.—During ascent to high altitude there is a point at which breathing becomes altered. This varies in different individuals, but it has been noted as low as 4,000 feet. At about 12,000 feet altitude the increased depth in breathing amounts to between 20 and 100 per cent increase in lung ventilation. With further ascent there is a greater increase in depth of breathing, and at around 20,000 feet each inspiration may amount to 600 to 1,200 c.c. of air. The rate of respiration changes very little at any altitude and even under extreme conditions seldom increases more than 5 breaths per minute.

Death from altitude sickness in the normal organism is probably always due to a failure of the respiratory center. This may occur at different altitudes, depending on the duration of exposure. It is believed that an ascent to about 16,000 feet might eventually prove fatal in some cases. Above this altitude the exposure period necessary to produce death is progressively shortened, such that at 25,000 feet altitude and above, death may occur at any time after twenty to thirty minutes.

Most of our knowledge concerning the response of the cardiovascular system to altitude has been worked out by Schneider and Schneider and Lutz.³ They found that there were two types of reactors: "fainters" and "nonfainters." Of those tested 46.7 per cent were in the former classification and 53.3 per cent in the latter.

The fainters are those in whom the lower centers, which control heart rate, vascular tone, and the rate and volume of breathing, suffer paralysis before the higher or psychic centers are affected.

The nonfainters exhibit a failure of the psychic centers before the cardiac, vasomotor, and respiratory centers become seriously affected. A majority of these individuals sit erect and the physiologic processes continue to function normally for a few moments after consciousness is lost.

During ascent the pulse first begins to react at widely different intervals between 4,000 and 14,000 feet altitude. From the initial point of reaction on, the pulse tends to increase until the limit of endurance is reached when the mean increase of nonfainters is 28 beats, and that of fainters is 26 beats per minute. Accelerations of 62 beats per minute have been noted.

The blood pressure, like the pulse and respiration, may show a beginning change at 4,000 feet altitude. During ascent nonfainters may show a gradual rise of systolic pressure at altitudes of between 8,000 and 12,000 feet, but beyond that level there is a slow fall with increase in pulse pressure. In fainters the blood pressure is characterized by a sudden terminal diastolic fall. At a sustained altitude of 8,000 to 16,000 feet the blood pressure tends to return to normal values.

The effect of altitude on the heart is not, as many persons believe, due principally to the increased load but almost entirely to the lack of oxygen supply to the heart muscle. While it is true that the pulse rate increases and that in some cases the blood pressure rises, these changes are no more noticeable than would be seen in mild exercise. The effect of anoxia on the heart muscle is the same as that for any other tissue and, as pointed out above, the heart will continue to function long after the respiratory centers have become paralyzed. The contention that dilatation of the heart frequently occurs from moderate degrees of anoxia has been found in error.

The electrocardiographic changes from anoxia consist essentially of a lowering or inversion of the T-waves, a depression of the R-T interval, and sometimes a deformity of the QRS group.

With reference to the problem of flight with an abnormal heart we know from the experimental results obtained by Schneider and Lutz,³ Graybiel, and others,⁴ that anoxia has a detrimental effect. The seriousness of the effect is proportional not only to the altitude and the duration of exposure but also to the amount of cardiac impairment. The type of heart lesion does not seem to be as important as the amount of cardiac reserve, nor does the increased demand on the heart seem to be as important as the effect of anoxia on the heart muscle.

The power of the external ocular muscles has been found to be decreased above 15,000 feet. Above 15,000 feet visual acuity and light perception become lessened, but some vision is retained up to the point of unconsciousness.

Hearing is usually not affected as quickly as vision, and 16,000 to 18,000 feet may be reached before this sense is noticeably affected. Above this level, however, it decreases rapidly, and at 20,000 feet the noise of the airplane motor may be entirely imperceptible.

At altitudes of about 14,000 feet and above there is a progressive deterioration of voluntary muscular control. The first sign to appear is incoordination of the finer muscular movements, followed by slowing of movements, tremor, and finally paralysis.

By far the most interesting and the most striking objective symptoms of altitude sickness are those due to a change in behavior. These have been studied extensively by McFarland⁵ both in flight and in the laboratory.

Most recent writers agree that there are no significant psychologic changes from anoxia even during prolonged flights at altitudes below 9,000 feet. Above this altitude, however, psychologic changes begin to appear, and the degree of change, as in the case of physiologic processes, is in proportion to both the altitude and the duration of exposure. These effects consist of a slight decrease in immediate memory and the onset of psychologic complaints. At about 14,000 feet altitude handwriting begins to become impaired, and there may be a change in moods, more or less characteristic in each individual; there may be sleepiness, lack of volition, and lethargy, or there may be a temporary stimulation with euphoria.

At about 18,000 feet the effects become much more pronounced. At this point, in addition to a definite decrease of sensory perception, the impairment of neuromuscular control is quite marked, the field of attention is narrowed, and the higher mental processes are affected, as indicated by the loss of memory, the development of irrational or fixed ideas, and the loss of sound judgment and self-criticism.

Between 20,000 feet and the point at which unconsciousness occurs, the psychologic effects are very profound. Simple reaction time tests and simple sensory and motor responses become altered. There is a marked loss of neuromuscular control, and there may be twitching, rhythmical movements, or even paralysis. Awareness of the lapse of time is lost, as well as volitional control, except that there is a great persistency in attempting to carry out an assigned task. Explosive emotional outbursts may occur, with periods of laughter, anger, or pugnaciousness.

Subjective Symptoms.—There are few, if any, other conditions known to medicine which produce such profound changes in the body, or which may even produce death without creating more pronounced subjective manifestations than those experienced in acute altitude sickness. In fact, it is not at all unusual for a person to become unconscious from the effects of the latter without being aware of any change from the normal. However, some individuals do experience various mild subjective symptoms during an attack of altitude sickness, and many suffer more or less afterwards.

At altitudes of 12,000 feet or above individuals may react psychologically in one of two general ways. Some feel tired, depressed, or sleepy, and tend to fall asleep. Others, however, will have the opposite reaction and become euphoric, with outbursts of hilarity, uncontrolled laughter, or pugnaciousness which do not appear ludicrous or unnatural to the individuals concerned, although they are usually aware of their moods. At an altitude of about 25,000 feet coma occurs. This comes on rather suddenly but not unpleasantly and usually without any subjective warning.

In contradistinction to the relatively mild or even total absence of subjective symptoms while at high altitude, the after effects may be very severe. This appears to be due to the fact that the sensory functions of the body return to

normal almost immediately upon returning to low altitude, while the other general systemic effects tend to persist for some time afterwards, provided the anoxia has been very severe, or even in mild cases if it has been prolonged.

Flying at 10,000 to 12,000 feet for a period of two to four hours is usually followed by a dull headache and a sense of fatigue both of which may persist for several hours, the fatigue generally being the more prolonged. As the length of the flights at the above altitudes increases, the aftereffects increase in proportion both in intensity and duration.

Exposure to an altitude of 15,000 to 18,000 feet for a period of two to six hours may be followed by a very severe intractable headache, nausea, vomiting, dizziness, mental confusion, muscular weakness, and even complete prostration. At higher altitudes these same effects may appear with shorter exposures, until at about 24,000 feet fifteen or twenty minutes may be all that is required to produce them. The more severe the symptoms the longer they persist, and as long as forty-eight to seventy-two hours may be required for complete recovery.

If oxygen instead of air is breathed at high altitude, the partial pressure of the oxygen can be maintained normal and altitude sickness prevented up to 33,000 feet. Above that altitude the partial pressure drops below normal and reaches zero at 50,300 feet,⁶ even while breathing pure oxygen. Between these two altitudes all the symptoms of altitude sickness occur, as described above, with unconsciousness appearing at about 43,000 feet. From this it is evident that even with oxygen high altitude flying is definitely limited.

DECREASED ATMOSPHERIC PRESSURE

The decrease of atmospheric pressure with ascent may produce five different pathologic states in the body. Three of these are brought about by expansion of the gases contained in the body cavities.

Probably the most frequent difficulty experienced by passengers and pilots in flight is with reference to the middle ear. The middle ear is an air-filled cavity which is ventilated through the eustachian tube. The eustachian tube is normally collapsed with its walls in apposition under ordinary circumstances and is open only during swallowing, yawning, and other physiologic acts. As a consequence, during a change of altitude either a positive or a negative pressure builds up in the middle ear unless the eustachian tube is voluntarily opened. If for any reason the eustachian tube is stenosed, which may occur even from a mild coryza or pharyngitis, the middle ear cannot be ventilated and a marked change of altitude may then rupture the eardrum.

A like condition occurs with reference to the sinuses when their openings are blocked, in which case, during a change of altitude, marked trauma and severe pain may develop.

Another condition which may occur is abdominal distention, since the gastrointestinal gases expand in direct proportion to the decrease of atmospheric pressure during ascent.

Since the above-mentioned effects may occur in normal individuals, it is obvious that those suffering from various pathologic states may be even more adversely affected. Thus any inflammation or infection of the middle ear or the

nasal accessory sinuses may be aggravated by flight. Expansion of the gastrointestinal gases will, of course, affect those with hernia, recent abdominal operative wounds, gastric or duodenal ulcer, acute or chronic appendicitis, or obstruction of the intestinal tract.

The fourth pathologic state which may arise in high altitude flight is *aero-embolism*,⁶ a clinical condition in aviation corresponding to compressed air illness in deep sea diving. That the compression of an individual followed by a rapid decompression would result in illness has been recognized for over one hundred years. The exact cause of this condition was not definitely known, however, until the investigations of Bert were published in 1878. Bert showed that the symptoms were due to the liberation of a gas in the body and that this gas was composed chiefly of nitrogen. *Aero-embolism* is a condition caused by the same general process that causes compressed air illness, with the exception that the former occurs from compression to 2 or more atmospheres followed by decompression, while the latter occurs from decompression from 1 atmosphere pressure or less.

During ascent in aircraft, or in any other situation in which the atmospheric pressure is decreased, the internal partial pressure of the body nitrogen is above that of the nitrogen in the lungs, and the tissues are, therefore, supersaturated. As a consequence, the nitrogen dissolved in the blood begins to be liberated in the lungs, the nitrogen in the tissues begins to enter the blood stream, and by this dual process the body tends to rid itself of its excess nitrogen. If the ascent is slow enough so that the nitrogen in the body can be eliminated and not reach approximately double its normal saturation at the prevailing altitude, nothing unusual will occur. If, on the other hand, concentration of nitrogen in the body becomes more than double its normal saturation value at any altitude pressure, the nitrogen gas will come out of solution and form bubbles to which is added some oxygen, carbon dioxide, and water vapor from the surrounding blood and tissues.

Since the elimination of nitrogen from the body is entirely through the blood stream, those parts of the body or those tissues which have the poorest blood supply will be the least able to lose their excess nitrogen. The blood is the first to lose its excess nitrogen, the body tissues (other than fatty tissues) second, and the fatty tissues last, the delay in the latter being due to both its higher nitrogen content and to its poorer blood supply. That this is essentially correct is indicated by the fact that with rapidly decreased atmospheric pressures, gas bubbles are found in the spinal fluid and about the spinal cord at 18,000 feet altitude, while bubbles in the blood and body tissues generally have not been found below 30,000 feet altitude.

It is obvious that if one ascended slowly enough to high altitude, the nitrogen of the body would be eliminated as fast as it tended to become excessive. Therefore, the rate of ascent is important, since the nitrogen content of the tissues must be at least twice normal at any given atmospheric pressure before it will appear as bubbles. During ascent bubbles first appear in the spinal fluid, but at the present time no experimental data have been obtained which give the maximum rate of ascent that can be used without these bubbles being

formed; it has been calculated that they would develop at any ascent of more than 78 feet per minute.

The symptoms of aero-embolism are identical with those of compressed air illness and consist principally of joint pains, paralysis, paresis, hyperesthesia, embolism, pulmonary edema, and formication, neurodermatitis, or pruritus of the skin.

The treatment, of course, is the returning of the patient to a region of higher atmospheric pressure, which in the case of high altitude flight simply involves a return to lower altitudes.

In addition to active treatment there is a prophylactic measure available which may be utilized. This consists of the inhalation of pure oxygen for one-half to one hour before ascent. This eliminates most of the nitrogen from the body and hence the cause of the disease.

FUTURE TRENDS

That the cold of high altitude can be controlled by closing and heating cabins, that altitude sickness can be controlled up to 33,000 feet by the breathing of oxygen, and that attacks of aero-embolism can also be controlled by the breathing of oxygen have been indicated. A new method of controlling these problems, together with all other clinical entities peculiar to high altitude flight, has recently reached the stage of practical development. This involves the use of a pressure cabin. It will be recalled that, except for cold, all medical problems of high altitude flight arise either directly or indirectly from a decrease of atmospheric pressure. From this it should be evident that if an airplane cabin were sealed pressure-tight and the contained air maintained at or near sea level pressure, all these problems would cease to exist. This theory has been tested and found to be successful.

While pressure-cabin aircraft may differ greatly in details of construction and operation, they all incorporate the following general features: Openings in the cabin walls, such as windows, doors, and control cables, etc., are sealed airtight against the internal positive pressure. An air compressor of some type is used to take in atmospheric air, compress it, and force it into the cabin under pressure. A cabin exhaust valve is provided to transmit the air in the cabin back to the outside atmosphere and thus allow the entrance of fresh air from the compressor. Strangely enough this system also takes care, to a large extent at least, of the high altitude cold, for the incoming air is heated by compression.

The pressure cabin is ideally suited for use on commercial air lines from the passenger standpoint, since it not only eliminates the oxygen question but also does away with distressing symptoms from the ears and other parts of the body due to barometric pressure changes. From the operator's standpoint greater speed and economy can be obtained by high altitude flight, provided the flights are of sufficient length. Based on present trends, it is believed that transcontinental and transoceanic aircraft will practically all be of the pressure-cabin type within the next five to eight years, and that within ten to twelve years practically all transport lines will operate pressure cabins exclusively. This latter is based on the fact that the ear and sinus problems in passengers will

always be with us at high or low altitudes until the pressure of the cabin is controlled within a very narrow range. The pressure-cabin airplane is easily the greatest contribution to human comfort and safety in flight that has ever been developed.

METHODS OF RESUSCITATION*

RALPH M. WATERS, M.D., MADISON, WIS.

IF IT exists, the opportunity to bring the dead to life is rare. The sudden acute failure of the function of respiration or of circulation, or both, may result in a condition resembling death from which recovery is possible if proper measures are promptly instituted. It is to such "proper measures" for the restoration of respiration or circulation that the term "resuscitation" is, rightly or wrongly, often applied. The abundant margin of safety maintained by nature in the case of almost every other physiologic function is lacking in the matter of the transport of oxygen from environmental atmosphere to the tissues. Continuous adequate breathing, together with adequate blood flow, constitutes this transport mechanism. The total failure of either respiration or circulation must be extremely brief if the individual is to survive.

The length of time during which interruption of oxygen transport may be compatible with complete recovery has been the subject of much speculation. It depends upon the condition of the cells at the instant of complete interruption of transport and varies from a few seconds to nine or ten minutes. The individual suffering from severe cardiac decompensation may die within fifteen seconds of the initiation of complete respiratory obstruction or after three breaths of pure nitrous oxide. At the other extreme, a healthy athlete, after a period during which he breathes pure oxygen, may safely stay under water for nine or ten minutes. Recovery of the vegetative functions has been reported following periods of arrested oxygen transport of considerable duration.^{1, 2} The more specialized centers of the central nervous system tolerate oxygen deprivation poorly. Failure of recovery may be preferable to recovery accompanied by blindness, amnesia, idiocy, or other defects of the higher centers. Methods of resuscitation to be effective must be instituted promptly and must transport oxygen efficiently until normal activity is restored.

Fisher³ traced the evolution of methods of resuscitation. He described in more or less detail, almost a hundred methods, 77 of which were attempts to perform artificial respiration, and 18 were designed to re-establish respiration by sensory stimulation of one sort or another. With the exception of cardiac or vascular massage, which is performed purposely or incidentally in many methods of artificial respiration, Fisher mentioned only four procedures involving direct attack upon the circulatory system.

Other than by the replacement of deficient blood volume by intravascular fluid injection, it is probable that less than 4 per cent of candidates for resuscitation can be benefited by direct attempts to replace, restore, or stimulate the cir-

*From the Department of Anesthesia, University of Wisconsin Medical School.

culatory mechanism. The surgical nature of direct attack upon the heart or blood vessels makes for delay and may interfere with efficient artificial respiration. The intravascular, intracardiac, or other administration of so-called analeptics, when the tissue cells already suffer oxygen want, may add insult to injury. The application of the electric current to re-establish heart action, suggested by Snow⁴ and others⁵; the desensitization of the fibrillating heart by topical application or vascular injection of procaine, as suggested by Beck⁶; the intracardiac injection of adrenalin, and other specialized procedures demand knowledge and equipment not likely to be available under the usual circumstances when methods of resuscitation are needed.

Prompt restoration of oxygen, then, to the cells of the central nervous system is our primary object. Except in very unusual circumstances, the introduction of oxygen into the circulation other than through the alveolocapillary membrane^{7, 8} has not proved satisfactory. Prompt, efficient, and yet not traumatic or overvigorous, artificial respiration is, therefore, the sheet anchor of resuscitation.

ARTIFICIAL RESPIRATION

If there are 77 different methods of performing a technical procedure (and Fisher did not exhaust the literature by any means¹), it indicates one of two things. Either no known method is satisfactory, or the method is of little importance compared with the understanding with which the method is applied. The latter may be presumed to be the case with methods of artificial respiration. Success was reported by the originator of each of the 77 methods. Why? Undoubtedly some of the individuals "resuscitated" would have re-established adequate oxygen transport without treatment. However, the originator of a method in every case had devoted time and thought to the problem involved. His effort to maintain a substitute for normal respiration was performed intelligently, and the result was satisfactory. However vigorously the chest be "squeezed" or the upper air passages "blown into"—be it by hand or machine—unless oxygen is replenished in the alveoli, the result will be valueless. Not infrequently has an efficient method of artificial respiration been applied in the presence of an obstructed glottis and with negative results. All too frequently do we waste valuable seconds or even minutes in procuring a piece of mechanical apparatus or a cylinder of oxygen to treat respiratory failure, when our own hands or our own respiratory muscles could have been used instantly to coax or force air containing oxygen into the victim's lungs.

It is possible, as demonstrated by Robert Hooke in the seventeenth century, and popularized by Meltzer and Aner in 1909,⁹ to perform "respiration without respiratory movement." This means that if the deeper air spaces are flushed with a continuous stream of air or oxygen, an adequate tension of oxygen can be maintained in the alveoli, and the carbon dioxide tension can be kept below normal, so that there is insufficient acid stimulus at the respiratory centers to initiate movement. Only under unusual circumstances is such a technique of replacing normal respiration thought advisable in present-day practice. If sudden respiratory arrest is encountered in a viable patient, good practice

Prompt, efficient, and yet not traumatic or overvigorous, artificial respiration is, therefore, the sheet anchor of resuscitation.

ARTIFICIAL RESPIRATION

If there are 77 different methods of performing a technical procedure (and Fisher did not exhaust the literature by any means), it indicates one of two things. Either no known method is satisfactory, or the method is of little importance compared with the understanding with which the method is applied. The latter may be presumed to be the case with methods of artificial respiration. Success was reported by the originator of each of the 77 methods. Why? Undoubtedly some of the individuals "resuscitated" would have re-established adequate oxygen transport without treatment. However, the originator of a method in every case had devoted time and thought to the problem involved. His effort to maintain a substitute for normal respiration was performed intelligently, and the result was satisfactory. However vigorously the chest be "squeezed" or the upper air passages "blown into"—be it by hand or machine—unless oxygen is replenished in the alveoli, the result will be valueless. Not infrequently has an efficient method of artificial respiration been applied in the presence of an obstructed glottis and with negative results. All too frequently do we waste valuable seconds or even minutes in procuring a piece of mechanical apparatus or a cylinder of oxygen to treat respiratory failure, when our own hands or our own respiratory muscles could have been used instantly to coax or force air containing oxygen into the victim's lungs.

It is possible, as demonstrated by Robert Hooke in the seventeenth century, and popularized by Meltzer and Auer in 1909,⁹ to perform "respiration without respiratory movement." This means that if the deeper air spaces are flushed with a continuous stream of air or oxygen, an adequate tension of oxygen can be maintained in the alveoli, and the carbon dioxide tension can be kept below normal, so that there is insufficient acid stimulus at the respiratory centers to initiate movement. Only under unusual circumstances is such a technique of replacing normal respiration thought advisable in present-day practice. If sudden respiratory arrest is encountered in a viable patient, good practice

dictates that we should initiate rhythmic exchange of alveolar atmosphere at once by the most available method at our immediate command.

TECHNICAL CONSIDERATIONS

Normal breathing while at rest is accomplished by intermittent exaggeration of the subatmospheric intrapleural pressure. It is brought about chiefly by synchronous contraction of the intercostal muscles and the diaphragm. Under stress normal breathing is probably a combination of active alternate increase and decrease of pleural pressures. When respiratory muscles cease activity, the lungs are held partly filled at atmospheric pressure by the negative pressure in the pleural cavities, in spite of the elasticity of lung tissue which is tending to collapse the lungs and force the contained atmosphere out. To maintain rhythmic exchange of the atmosphere in the alveoli, three physical changes and combinations of these are available:

- I. Intermittent exaggeration of negative intrapleural pressure.
- II. Intermittent increase of pressure in alveolar spaces.
- III. Intermittent decrease of negative intrapleural pressure.

I. *Intermittent Exaggeration of Subatmospheric Pressure.*—Silvester in 1858¹⁰ described a manual maneuver which accomplished artificial intermittent exaggeration of the negative intrapleural pressure in a manner simulating the normal. With a pad under the shoulders and the patient in the supine position, the arms are raised over the head elevating the ribs, the pleural negative pressure is increased, and air rushes into the lungs. When the arms are returned to the sides, the ribs fall, the pleural pressure becomes less negative, and air rushes out of the lungs. He recommended that the arms be pressed against the ribs as they are returned to the sides to aid in expiration.

Willez previous to 1881,¹¹ and more recently Drinker¹² and others, have popularized mechanical respirators, surrounding the trunk or the whole body below the neck with an airtight box in which the pressure can be intermittently reduced, thus raising the ribs and the abdominal wall and imitating the combined effect of intercostal and diaphragmatic action on the intrapleural pressure (see under III).

II. *Intermittent Increase of Pressure in Alveolar Spaces.*—The intermittent transmission of positive pressure to the alveoli through the air passages was probably the first method of artificial respiration described. Several passages in the Bible have been so interpreted.^{13, 14} Vesalius maintained respiration by this means while he demonstrated the movements of the heart when the anterior thoracic wall of animals had been removed. Intermittent direct inflation of the lungs by hand pressure on a rubber breathing bag attached to a face mask or artificial airway is the common method used by the anesthetist when respiration ceases. He finds it possible to maintain adequate ventilation in this manner.^{15, 16}

Numerous mechanical devices have been constructed to inflate the lungs intermittently. The fireside bellows is said to have been used by Vesalius. Goodwyn in 1786 described an especially made syringe,¹⁷ and every generation since that time has had its favorite for the purpose.

III. *Intermittent Decrease of Negative Intrapleural Pressure.*—To decrease the negative or subnormal pressure in the pleural cavities and thereby cause atmosphere to rush out of the alveoli through the air passages (followed by passive inspiration), the thoracic cage must be made smaller by depressing the ribs or pushing the diaphragm upward, or both. The Schafer prone pressure manual method of artificial respiration¹⁸ typifies the application of this principle. Simple intermittent pressure on the ribs or abdominal wall does the same. Mechanical devices by which the trunk or part of it is inclosed in an airtight rigid container can be used to decrease the negative intrapleural pressure if positive pressure is intermittently applied inside the container.

The combinations of these three principles of maintaining atmospheric exchange are many and varied. Synchronous application of I and II, alternation of II and III, and alternation of I and III have been advocated. Accomplishment is suggested by alternating changes of position of the whole body, by manual manipulation of various parts, and by cumbersome¹⁹ or beautifully intricate²⁰ machines. Hand power, foot power, electric motors, and compressed gas, all have been and are being used to motivate such equipment.

In general, it may be said that manual maneuvers or direct inflation of the lungs from the operator's own respiratory tract have the advantage of instant availability and intimate personal relation to the effort, resulting in the likelihood that the rescuer will more readily appreciate defects in the methods, such as an obstructed airway and inadequate or excessive exchange. The actual method of performing artificial respiration is relatively immaterial. In circumstances where the respiratory tract is free of contaminating material, direct inflation of the lungs by blowing intermittently through the patient's mouth or nose is probably the most readily available. The oxygen cylinder, breathing bag, and mask ought to be available in hospitals and emergency kits. The Silvester method is as efficient as other manual methods.²¹ If the tract is contaminated by foreign material, as after vomiting or drowning, and suction apparatus is not available, the Schafer prone pressure maneuver is safer. The instant application of some method of intermittent exchange, when natural effort ceases, is all important.

Mechanical apparatus is constructed partially of rubber which deteriorates, of intricate machinery which gets out of order, of weighty substances which are difficult to transport. Delay in the application of apparatus is the rule, not the exception. If resuscitation is attempted with apparatus as promptly and as intelligently as with manual maneuvers or direct inflation, the result may be as good, but not better. The enrichment of the atmosphere with oxygen is valuable in either circumstance, and trauma or overventilation,²² as well as inadequate atmospheric exchange, may result from our efforts. A mechanical respirator is as safe and as efficient as the physiologic intelligence and technical skill of the person who operates it and no more so. Comprehension of the physiologic factors involved and intelligent direction of the effort by an experienced physician are essential whatever the method employed.

Whether the rhythmic change in intrathoracic pressure experienced in normal breathing has an important influence upon blood flow has never been

satisfactorily determined. In desperate circumstances intermittent high pressure (40 to 60 mm. of mercury) chest inflation in performing artificial respiration with oxygen has been observed to propel blood through the vessels.²³ Whether the usual rational efforts at performing artificial respiration may aid in maintaining an adequate blood flow has not been determined. Clinical experience leads me to believe that pulmonary circulation, at least, is influenced by rhythmic filling and emptying of the lungs. Attempts to substitute "respiration without respiratory movement" during open chest operations have been associated, after a period of fifteen or twenty minutes, with circulatory depression that appeared to be dependent upon the absence of the movement of the lungs, since circulation seemed to improve when intermittent inflation was resumed.

RESUSCITATION AND THE PHYSICIAN

It is obvious that there are many maneuvers capable of maintaining satisfactory exchange of the alveolar atmosphere when normal respiration ceases. Two factors more important than the method by which exchange is brought about are (a) the promptness with which the artificial method is initiated after normal activity has ceased; (b) the intelligence and physiologic understanding with which the method is applied. Because of a realization of the necessity for promptness, lay rescue squads were instituted and trained to function in the absence of a physician until one could reach the patient. They have served a useful purpose, but, as a result, the medical profession and the public have come to look upon "resuscitation" as a nonmedical effort. Medical schools neglect to teach the clinical application of physiologic principles to the care of acute respiratory morbidity. Many young physicians come to their internships dependent solely upon such knowledge and skill as they have gained from their Boy Scout training. Practitioners of medicine rush to the telephone to call rescue squads from the police and fire departments while patients die who could be rescued. To the disgrace of present-day medical education, sudden failure of respiration is not a rare cause of death in the wards and operating rooms of the modern hospital.

Medical training must include knowledge and skill in the rapid re-establishment of a free and open airway. Specific instruction in the anatomy of the air passages, as it applies to the transfer of atmosphere to and from the alveoli, the use of a simple laryngoscope—its advantages and dangers—the nontraumatic insertion of an artificial airway, the use of suction or gravity to remove contaminating foreign substances, and the physiologic principles of oxygen and carbon dioxide transport, all these as well as methods of artificial respiration, must be included in the training of a physician. Equipped with such knowledge and skill, the physician will instinctively do the right thing in a moment of emergency. Clearing the airways and accomplishment of exchange will be prompt because they are instinctive. Facility in the care of respiratory failure can be taught by the department of anesthesiology. Anesthetized patients can be used as demonstration material to the advantage of patients as well as students. If experience is acquired when no serious emergency exists, the loss of time and waste motion characteristic of excited persons in an emergency may be avoided.

SUMMARY

"Resuscitation" is not the resurrection of the dead, but the re-establishment of oxygen transport from atmosphere to body tissues when either factor in that transport has been suddenly interrupted.

The restoration of circulation, once it ceases, is rarely possible. Treatment directed at the heart and blood vessels other than the injection of blood and other fluids is indicated only in unusual circumstances.

The most logical procedure in emergencies demanding resuscitation is the provision of (a) a free and unobstructed airway; and (b) intermittent exchange of alveolar atmosphere containing excess oxygen.

Mechanical devices will rarely be needed if instant intelligent aid is at hand. They do not produce more adequate exchange than direct inflation from the operator's own lungs or manual maneuvers, nor higher concentration of oxygen than a simple oxygen cylinder, breathing bag and mask, and they may over-ventilate or traumatize the lungs. Their sole advantage is seen in cases requiring long periods of artificial respiration, such as drug poisoning, paralyses, and the like, when the operator might become exhausted. Rarely will such cases come under the classification of "resuscitation".

Finally, the re-establishment of the physiologic functions which transport oxygen is within the physician's province. The fact that some doctors even in hospital practice are dependent on lay rescue squads is a reflection on medical education.

CLINICAL PATHOLOGY: PAST, PRESENT, AND FUTURE*

ROBERT A. KILNUFFE, A.M., M.D., ATLANTIC CITY, N. J.

EVEN the most casual observer must admit that medicine—which includes all that pertains to the recognition, management, and control of disease—is in a constant state of flux. So many, so varied, and so continual have been the advances in the last twenty-five years that the limits of the future may almost be thought to be defined only by the limits of the imagination. Particularly may this be said of that phase of medicine which has come to be known as clinical pathology, at long last officially recognized for what it has long been in actuality—a specialized, and highly specialized phase of the practice of medicine.

No one will deny that the first and most important step toward the solution of a clinical problem is the recognition of its nature. In other words, accurate diagnosis is the essential prerequisite for intelligent treatment.

When disease could be regarded as a manifestation of the wrath of vengeful gods, diagnosis was indeed an easy matter. But as the centuries rolled on, imperceptibly merging the past with the present, human nature became less credulous, and concepts of disease less and less associated with dogmatic formulas and more and more dependent upon attempts at the logical and rationalized interpretation of observed phenomena.

Inevitably it came to be realized that it was not enough to give the disease a name. And as the realization of the necessity for more than this became keener, the more persistent and searching were the endeavors to uncover the underlying, basic mechanism upon which the phenomena of disease depend. Fascinating as is the story of these developments in retrospect, it cannot be told here. For the way was long and devious, the forward steps slow and toilsome, and the history of medical progress, though colorful, cannot be told briefly. Suffice it to say that each advance made more clear the concept upon which modern medicine is based: That just as health, in the last analysis, is a condition characterized by perfect and frictionless functional efficiency, so disease, on the contrary, is the manifestation of disturbance, alteration, or loss of function.

From this concept clinical pathology was derived. For while it is obvious that the skilled physician is characterized by the degree to which he has cultivated his powers of observation as well as—what is equally important—the degree to which he has developed ability to interpret the significance of what he observes, it is equally obvious that there are inescapable limits to what may be ascertained by clinical observation alone.

Observation, which signifies the accumulation of pertinent data by all ordinary means, may well lead, for example, to the clinical suspicion that the patient is a diabetic. But no amount of ordinary observation suffices to demon-

*From the Laboratories, Atlantic City Hospital.

strate the essential, pathognomonic evidence of the disease—hyperglycemia. For this, recourse must be had to the specialized methods of the clinical laboratory; and so there came into being what, for a time, it was customary to speak of as “laboratory medicine” in which the “test” was the thing.

Now while laboratory procedures are best and most properly thought of as specialized phases of the examination of the patient, the early days of “laboratory medicine” present aspects at times suggesting merely an elaboration of an older order exemplified by the urologist of the past who, from his stand in the market place, from a paucity of data drew pontifical prognostications of extraordinary inclusiveness. It seems not altogether unjust to see some faint shadow of his counterpart in the surgeon of old, for whom a white cell and differential count plumbed the depths of scientific medicine, or the clinician of the same day for whom glycosuria and diabetes were synonymous, and albuminuria made the diagnosis of “Bright’s disease.”

Medicine, like all human endeavors, has a tendency to go to extremes. If this so-called early phase of laboratory medicine evidenced a tendency to erect imposing diagnostic structures upon somewhat slender laboratory foundations, the phase that followed was often characterized by a multitude of laboratory reports as *ipso facto* evidence of a prodigal expenditure of all the resources of medical science.

In this streamlined present we are likely to think of those days as very long ago indeed. But it was only in 1924 that MacCarty¹ commented that in a series of 60,645 patients there were recorded 225,785 laboratory tests, an average of over 3 per patient. This shows, MacCarty adds, that “clinicians recognize that the diagnosis of disease is no longer covered by history, inspection, palpation, and auscultation.”

It may be further commented that the series in question comprises cases seen in a well-organized and outstanding clinic and that the laboratory procedures in question may, therefore, well be assumed to have been clearly indicated and wisely chosen as likely to be truly informative. This should be emphasized for it cannot well be denied, and certainly will not be denied by directors of hospital laboratories in general, that such laboratories are not infrequently called upon for examinations not always productive of essentially significant data. In other words, it can safely be said that a definite number of laboratory reports constitute “routine” procedures mainly for record purposes, and that others are neither necessarily wisely chosen, truly indicated, nor likely to be productive of clinically applicable or utilizable information.

If there should be a desire to question this, proof can be found in the requisitions for “blood chemistry,” for “general examination,” and so on, from the experience of almost any clinical pathologist. And if this is true of hospitals where the staff is presumably chosen on the basis of attainments, no comment is required on the “office laboratory” where the technician of varied training reigns supreme even though she may be simply the office attendant trained by the clinician.

Few have been quicker than the clinical pathologist to recognize and decri what, later, clinicians perhaps more loudly and frequently proclaimed: That the clinical value and utility of laboratory procedures is based essentially upon their

critical selection in accordance with the particular clinical problem at hand, and equally essentially upon the intelligent and critical evaluation of their results. It cannot be overemphasized that the methods of the laboratory are essentially specialized phases of the examination of the patient, the purpose of which is to detect and to measure alterations in function, the essential phenomena of disease whose existence, degree, and intensity can seldom be ascertained in any other way.

Once it is appreciated that the clinical value of any laboratory procedure depends, not upon its nature, but upon the interpretation of its results, the inevitability of the evolution of the clinical pathologist becomes apparent. For as the investigations into the essential and interlocking concomitant phenomena of disease embraced a necessarily widening field and developed into more and more complex and inclusive phases of physiology, immunology, serology, biochemistry, and the related phenomena of tissue growth, destruction, and repair, "laboratory medicine" became less and less primarily concerned with methods and technique and more and more focussed upon underlying basic principles and applications.

Inevitably the cloistered pathologist of old, engrossed in the study of the aftermaths of disease as evidenced in the dead, gave way to the *clinical* pathologist whose interest lay in the phenomena of disease and their development and progress in the living patient.

In its early days clinical pathology may well have been regarded as a specialty in which it was relatively easy to become skilled and competent, principally because this was largely an era of technical developments and the interpretation of laboratory procedures seemed relatively simple and well defined. But as the field became more and more inclusive, methods more complicated as well as more numerous and, particularly, their basic principles more intricate, clinical pathology became indeed complex, especially in its implications. Hence the clinical pathologist worthy of the name was forced to become to the limit of his ability an authority upon disease and its varied phenomena.

The clinical pathologist of today, therefore, is not, nor can he be, defined—as once was rather widely held—as an individual characterized mainly by manipulative dexterity. On the contrary, many an outstanding clinical pathologist would be the first to admit that in purely technical aptitude he may well be outstripped by many of his technical assistants. His place in modern medicine and his value to it rest not upon his ability to "make tests," but rather upon his ability to indicate, first, which avenues of laboratory approach may best be suited to the particular clinical problem, and, second, how the phenomena demonstrated by their results may best be interpreted in the light of all available data. Hence the term "*clinical* pathologist," for clinical training and clinical experience are essential. While he may learn technical minutia from books, just as he may learn signs and symptoms from books, he must learn medicine—of which clinical pathology is a phase comprehensive in its implications—at the bedside from a study of the patient.

That clinical pathology in its most desirable aspects represents a coordination of the clinical and laboratory aspects of disease is exemplified by the fact that outstanding surgeons and clinicians not infrequently have served an ap-

strate the essential, pathognomonic evidence of the disease—hyperglycemia. For this, recourse must be had to the specialized methods of the clinical laboratory; and so there came into being what, for a time, it was customary to speak of as “laboratory medicine” in which the “test” was the thing.

Now while laboratory procedures are best and most properly thought of as specialized phases of the examination of the patient, the early days of “laboratory medicine” present aspects at times suggesting merely an elaboration of an older order exemplified by the urologist of the past who, from his stand in the market place, from a paucity of data drew pontifical prognostications of extraordinary inclusiveness. It seems not altogether unjust to see some faint shadow of his counterpart in the surgeon of old, for whom a white cell and differential count plumbed the depths of scientific medicine, or the clinician of the same day for whom glycosuria and diabetes were synonymous, and albuminuria made the diagnosis of “Bright’s disease.”

Medicine, like all human endeavors, has a tendency to go to extremes. In this so-called early phase of laboratory medicine evidenced a tendency to erect imposing diagnostic structures upon somewhat slender laboratory foundations, the phase that followed was often characterized by a multitude of laboratory reports as *ipso facto* evidence of a prodigal expenditure of all the resources of medical science.

In this streamlined present we are likely to think of those days as very long ago indeed. But it was only in 1924 that MacCarty¹ commented that in a series of 60,645 patients there were recorded 225,785 laboratory tests, an average of over 3 per patient. This shows, MacCarty adds, that “clinicians recognize that the diagnosis of disease is no longer covered by history, inspection, palpation, and auscultation.”

It may be further commented that the series in question comprises cases seen in a well-organized and outstanding clinic and that the laboratory procedures in question may, therefore, well be assumed to have been clearly indicated and wisely chosen as likely to be truly informative. This should be emphasized for it cannot well be denied, and certainly will not be denied by directors of hospital laboratories in general, that such laboratories are not infrequently called upon for examinations not always productive of essentially significant data. In other words, it can safely be said that a definite number of laboratory reports constitute “routine” procedures mainly for record purposes, and that others are neither necessarily wisely chosen, truly indicated, nor likely to be productive of clinically applicable or utilizable information.

If there should be a desire to question this, proof can be found in the requisitions for “blood chemistry,” for “general examination,” and so on, from the experience of almost any clinical pathologist. And if this is true of hospitals where the staff is presumably chosen on the basis of attainments, no comment is required on the “office laboratory” where the technician of varied training reigns supreme even though she may be simply the office attendant trained by the clinician.

Few have been quicker than the clinical pathologist to recognize and decri what, later, clinicians perhaps more loudly and frequently proclaimed: That the clinical value and utility of laboratory procedures is based essentially upon their

intervening period there was much to indicate that the trend of clinical pathology was—if slowly—moving toward the ideal described.

If, on the one hand, there are more and more hospital laboratory directors whose functions are truly those of coordinators, liaison officers between the laboratory and the wards, on the other, there are still hospital laboratory directors, physicians, who are denied a place on the medical staff; and others—many others—who are not physicians and whose training has been essentially purely technical.

Can the present trend continue? What will be the trend of the next quarter of a century? He would be brave indeed who would attempt to answer these questions with any assumption of finality. It is well, however, to take stock of the situation and to at least marshal the facts which may well govern it in the future.

It is a matter of fact and record that there are not at present enough competent and accredited clinical pathologists to go around. This is the reason why it is necessary for hospitals to skirt approval, so to speak, by the not always entirely satisfactory expedient of the part-time pathologist shared by several hospitals. It is also the reason for the somewhat anomalous situation in which directors of hospital laboratories are neither physicians nor truly clinical pathologists.

If the present supply of clinical pathologists is insufficient, what are the prospects for the future supply?

Now it will be admitted that for the development of a clinical pathologist as a finished product there must be, first of all, a clinical pathologist in embryo. Like physicians in general, clinical pathologists reach their peak of ability and skill only after long training and experience; and, again like physicians in general, not being immortal, they eventually cease to function. If there is need—as who can doubt?—for maintaining the strain, not to mention the desirability of increasing its numbers, they must be replaced as they wear out, and such replacement can come only from those who follow willingly in their footsteps.

It is food for thought that in these United States there are less than 500 clinical pathologists certified as such, by the American Board of Pathology; less than 1,000 on the rolls of the American Society of Clinical Pathologists; and very probably not more than 2,000 in all engaged, with varying degrees of propriety, in this field of medical practice. What provision is there to balance the inevitable decrease in these numbers arising from the fact that flesh is mortal?

It may be admitted, indeed, in these days when the economic aspects of medical practice are so constantly, vociferously, and at times even acrimoniously discussed—it is being generally admitted—that the practice of medicine has its business aspects. Certainly, if there are to be doctors, they and their families must be fed, housed, and clothed. This is equally true of those physicians who have chosen to be clinical pathologists.

If it can be believed, as it may be, that “the laborer is worthy of his hire,” it may well be pertinent to speculate upon the relation of economic aspects to the clinical pathologists of the future. For it cannot be denied that in some

measure these will be a factor in determining the future supply of clinical pathologists. And, if it is true that the trend of the present may, to some degree, forecast the trend of the future, this may well be pondered upon.

It seems entirely probable that the clinical pathologist practicing this specialty as a private individual will be eventually, if he is not now, a thing of the past. This assumption may be supported by various factors of which the following are not the least important: (a) The gradual invasion of the diagnostic and even the therapeutic phases of medical practice by state boards and departments of health under the aegis, and with the full encouragement and financial support of the Federal government. (b) The even more aggressive invasion of medical practice in all its phases by the programs formulated by the United States Public Health Service under its Surgeon-General. (c) The increasing invasion of medical practice by hospitals and other corporate bodies in connection with "hospital insurance" and "sickness insurance" plans.

While these may be regarded as the spearhead of the attack, among the auxiliary forces contributing to the extinction of clinical pathology as a phase of the private practice of medicine may be noted: (a) the "diagnostic" laboratory operated by the trained technician; (b) the purely commercially owned and operated "clinical" and/or "diagnostic" laboratory not infrequently attracting "business" by discounts, and so on; (c) the drugstore laboratory doing urinalyses with the help of the directions given in the pharmacopeia.

It could be truthfully said that these auxiliary forces could not exist nor survive except for the support given them by the practicing physician in general. But it is of little avail to point this out. If commercial laboratories suffer from attrition, it will result from the drain of the "office laboratory" which has numerically increased by leaps and bounds since the depression for very obvious, and in the main purely economic, reasons.

In the face of these facts the reluctance of young physicians to enter the field of clinical pathology is readily explainable, for at least one of the reasons for engaging in the practice of medicine is the belief that it offers chance of satisfactory remuneration. While this may come deservedly to the clinical pathologist who has achieved through his attainments the status of a coordinator, correlator, and consultant, or to him who becomes a specialist within a specialty—as the tissue or hematologic diagnostician—these must be preceded by long years of training. Under present circumstances it is hardly strange that small numbers are entering into the field of clinical pathology. It is somewhat strange that clinical medicine can observe with only little apparent interest, if not with equanimity at least without outward perturbation, the gradual disappearance of a phase of medical practice by attrition through attack on all fronts; it is strange because what can happen to any one specialty in medicine can also happen in greater or lesser degree to any other specialty as an individualized endeavor.

It is at times even painfully apparent that clinicians, for one reason or another, have shown some tendency to regard the problems of clinical pathology with apathy. It is also true, and may well become equally painfully apparent, that the problems of medicine as a whole cannot be divided into the problems of separate specialties. For just as the specialist cannot safely regard the

patient as consisting only of the particular part, organ, or function with which the specialty itself is mainly concerned, but must see him as a coordinated, interlocking whole, so the physician must look upon medicine as a whole and appreciate that what affects it in part may well have repercussions on the whole.

There are, without doubt, many reasons, some of them not easily defined, for the separation of clinical pathology from clinical medicine. It may be due in part to persistence of its association in many minds with its purely technical aspects; in part, it may arise from the very complexity of the subject which tends to make men think, not of clinical pathologists, but of immunologists, serologists, biochemists, bacteriologists, tissue diagnosticians, and so on, as if all these must necessarily be separate specialties, whereas, in present days, the clinical pathologist—if he is to play his proper part in the understanding of disease—must be oriented in all of these.

It must be admitted too, that clinical pathologists have not always been in the fore in emphasizing the true status of their specialty and their own status in the field of medical practice. The clinical pathologist, it is true, must by his deeds and his accomplishments demonstrate his worth in the general field of medical practice and, having done so, is entitled to receive—and, if necessary, should demand—the same professional status accorded to the specialist in any field.

As Inglis³ has recently reiterated: "A well-trained pathologist endowed with the true scientific spirit, one who can win the confidence of his clinical brethren, will prove to be a boon to any group of practitioners. In competition with none, he can, in his special field, be adviser to them all. If he is of the right calibre he will bring an interest into their work such as they never dreamed of, and, should there be some who feel overburdened with monotonous routine, he may save them from becoming mere carpenters and pillmongers of the profession. To do all this a man must be endowed with high qualities and that is why those who are devoted to pathology hope to attract to its ranks the very best of our graduates."

It is well that clinicians at large should be reminded of these facts, for clinical pathology is an essential phase of clinical medicine. There is today no escape from this important and pertinent fact.

There has been much discussion of the present trend toward the so-called "socialization of medicine." But there has been little apparent interest in, and still less apparent appreciation of, the fact that the socialization of clinical pathology is well on the way if, indeed, it is not already here in appreciable measure. Let it be noted well that when the socialization of one phase of medical practice is fully and openly accomplished, the socialization of others will inevitably follow.

Clinical medicine will do well to regard the present trend of clinical pathology with somewhat less lethargy and equanimity than is customary. It may not be altogether the part of wisdom to ignore the present problem of supply and demand in the field of pathology, to leave its solution to the future, or to accept as a solution the influx of the emigrée—unless, of course, it is felt that such an influx is an easy and acceptable answer to the problem of medical supply and demand.

Unless men of proper caliber can be induced to enter the field of clinical pathology, to spend the time required for prolonged and essential training, medicine in general will suffer, and hospitals—which must be looked upon as centers of post-graduate training—will be increasingly unable to fulfil the function and the destiny which are properly theirs.

It should be frankly said, as Inglis³ has said, “to choose for responsible pathological appointments refugee doctors with inadequate special experience, because they are willing to accept the remuneration and status of technicians, would be unwise.”

The future of clinical pathology and, indeed, the future of medicine itself, may well be said to rest on the lap of the gods and of a Delphian oracle to interpret or to prophesy there is no sign.

PROGRESS

TUBERCULOSIS—PRESENT AND FUTURE

GERALD B. WEBB, M.D., COLORADO SPRINGS, COLO.

IN MOST parts of the world where statistics have been kept the death rate from tuberculosis has been steadily declining for about one hundred years.

About 1780 the estimated death rate from consumption in England was 650 per 100,000 living inhabitants.

It is expected that the death rate in the United States will fall below 45 per 100,000 in 1940. According to Dublin, this will represent a decline of 37 per cent in the last ten years, and a decline of 61 per cent in the last twenty years. In forty years the death rate has dropped 76 per cent.

It is probable that tuberculosis has waxed and waned in different countries during the world's history. Historical studies suggest that an epidemiologic period may run over two hundred years.

In London there was a high death rate in 1650 which then declined and rose again to a high peak in 1780.

We are now approaching the lower level of a declining cycle and with the enlightenment which is ours today a new cycle should never begin. It is curious that in studying the present decline, which is common to most countries where statistics are available, that this decline has been almost continuous and that the discovery of the bacillus in 1882, the increasing isolation of the tuberculous in sanatoriums since 1900, and the increase in collapse therapy since 1912, have not definitely accelerated the decline.

In this country the problem is still a serious one among the colored population and among the Mexican residents. In spite of the excellent work of clinics and agencies, many "carriers" of the disease continue to be undiscovered.

Relapse is still too frequent and this is often the result of too short a sanatorium regime as well as lack of aftercare. The time will come when every open case of tuberculosis will be segregated. This will mean that many States must increase their sanatorium beds. Approximately 600,000 individuals in this country have active tuberculosis. Only 90,000 sanatorium beds are available when there should be 150,000.

Thanks to the Department of Agriculture bovine tuberculosis is being rapidly eliminated. The more general pasteurization of milk has greatly lessened human infection by the bovine bacillus.

Teaching the detection, control, and eradication of tuberculosis should begin in the public schools. Children should be taken into the fields to study Nature and to be shown the parasitic diseases of the flora and fauna. With such beginnings the problem of human disease will be more easily imparted to them.

The detection of childhood tuberculosis by the increasing application of the intradermal skin test with the purified protein derivative has been a great advance in preventive medicine. Reactors can be carefully watched and their young lives can be controlled. In many communities Nutrition Camps have been established, and these are ideal for children who are below par or who react to tuberculin.

More and more x-ray examinations of young adults and children are employed; these examinations should be repeated at intervals on any person suspected of having the disease. The use of miniature films in surveys of large groups is of increasing value.

Since clinical and biographical studies show tuberculosis is frequently a family disease, physicians who attend such families have great responsibility.

For many years the trend of treatment has been against climate and also against the long rest regime, although both factors have been of definite value.

Since 1912 various forms of collapse therapy have been introduced. Many physicians feel such therapy should be instituted as soon as the diagnosis of adult pulmonary tuberculosis has been made.

Added to artificial pneumothorax we have thoracoplasty, phrenic nerve crushing, extrapleural pneumothorax, and other surgical procedures which now include the Monaldi procedure of suction aspiration of tuberculous cavities. It is possible the pendulum has already swung too far in the surgical direction. Artificial pneumothorax is gradually giving way to more and more thoracoplastic operations. In spite of the help from pneumonolysis too many results are incomplete and too many complications still occur from pneumothorax treatment. The length of treatment is also a handicap.

While physical examination still plays an important part in diagnosis and study, the x-ray has largely supplanted this and is of great value in guiding pneumothorax treatment. Laminagraphy is now adding more important information.

The present sees an increase in the use of the bronchoscope for the diagnosis of bronchial lesions and their treatment, for the detection of strictures when weighing thoracoplasty, and for final proof that sputum is negative.

In research laboratories the chemistry of the tubercle bacillus is being carefully studied, and what is of probably more importance the growth factors are being discovered.

All efforts to discover a chemotherapy treatment have failed. Numerous laboratories have investigated the value of sulfanilamide, of sulfapyridine, and other derivatives of these drugs, but no success has been obtained.

The increase of blood platelets in active and chronic tuberculosis has never been explained by laboratory workers.

Clinicians note "leads" which may be followed. Why, in patients with diabetes, who become infected, does the tubercle bacillus progress so rapidly? Why do certain families, who are prone to high blood pressure and to nephritis, seem so immune to tubercle bacillus destruction?

Clinicians have observed that in tuberculous families the children who resemble in constitution a parent who has belonged to the high blood pressure group have escaped serious infection when the children of the tuberculous parent's type died.

Why is there a lessened incidence of pulmonary tuberculosis in patients who develop hyperthyroidism?

Vaccination by B.C.G. (*Bacillus Calmette Guérin*) has gained in usage in Europe, and laboratories in this country have established some value in animals, especially with intravenous administration.

With the continued decline in the death rate a form of vaccination may not be necessary. Shortage of food may again increase the number of tuberculous victims on the continent of Europe. The improved housing and living conditions in the United States, together with the activities of the National and State Tuberculosis Associations, should assuredly prevent another serious rise in the tuberculosis death rate in this country.

CLINICAL AND EXPERIMENTAL

DISSECTING ANEURYSM OF THE AORTA*

CASE REPORT

ABEL LEVITT, M.D., F.A.C.P., DEXTER S. LEVY, B.A., M.D., AND
JAMES R. L. COLE, M.D., BUFFALO, N. Y.

THE relative infrequency with which the diagnosis of dissecting aneurysm of the aorta is made ante mortem has prompted us to report a case observed on the wards of the Edward J. Meyer Memorial Hospital. For many years this disease has been known to pathologists, but until recently the clinical observations have been few and the diagnosis has been made at post mortem. The true explanation of this probably lies in the fact that the disease is often confused with various intrathoracic or intra-abdominal conditions which it closely simulates. The relative infrequency of the ante-mortem diagnosis is more evident when it is realized that only twenty-five cases can be found reported in the literature.¹ The disease itself occurs predominantly in males between the ages of 40 and 60 years, in whom there is a usual history of hypertension. There is no pattern to be followed in the diagnosis, but certain features when present must be analyzed in proper combinations to eventuate the correct diagnosis.² These include: (1) the sudden onset of pain in a person with hypertension. This pain not infrequently radiates to other portions of the body but rarely the arms; (2) the presence of a rapid, enlarged heart with or without murmurs; (3) the presence of shock; (4) slight fever and leucocytosis; (5) dyspnea and cyanosis; (6) variation in the pulses between the upper and lower extremities.

There have been many theories advanced as to the cause of the disease, and the division into predisposing and exciting factors has been advocated.³ The predisposing factors include:⁴ (1) Virchow's view that most of these aneurysms arise on the basis of atheromatous ulcers. The fact that arteriosclerosis was not observed in some of the cases at necropsy makes this a tenable explanation in only a few. (2) Inflammation which may weaken the wall of the aorta sufficiently to predispose it to rupture. (3) Medial degeneration of the aorta, in which there is focal hyaline degeneration resulting in cyst formation, has recently been recognized as strongly predisposing to the disease.

With the presence of a predisposing factor, however, the problem of what is the actual causative factor presents itself. Here it has been agreed that two primary factors play a part: (1) physical trauma, and (2) internal trauma due to either emotion or exertion.

*From the Medical Service of the Edward J. Meyer Memorial Hospital (Buffalo City Hospital) and the School of Medicine, University of Buffalo.
Received for publication, October 16, 1939.

Pathologically⁵ the aorta usually shows an irregular tear which extends through the interior and partly through the media into which blood penetrates until it finds a plane of cleavage and begins to dissect. The blood enclosed in this sheath composed only of adventitia and media most often perforates at some point.

Clinically, as already indicated, certain features suggest the diagnosis. The patients are acutely ill and fail progressively, and the ultimate prognosis is poor, with death occurring in from a few hours to several days. In the differential diagnosis (1) coronary thrombosis, (2) embolism, (3) abdominal catastrophe, and (4) pneumonia are most frequently confused with the diagnosis.

Fig. 1.—A, The large oval represents the hemorrhagic mass over the right auricle. It extends around the base of the heart and aorta with compression. B, the fibrous tag on the pericardium where a similar large amount of clot was found partly organized; C, the dissecting hemorrhage above, in between the coats, and below outside of aorta continuous with hemorrhage A.

CASE REPORT

CASE 379362.—The patient was a white male, aged 51 years, whose occupation was a fireman. He was referred to the hospital on December 5, 1938, with a history of eight hours' duration. He complained of being awakened from his sleep by a sharp, excruciating pain, located diffusely throughout the lower abdomen, but more pronounced about the umbilicus. This pain radiated through to the back, and at the onset was accompanied by emesis on two occasions. No blood was present in the emesis, and the stools were normal in color and consistency. His past history revealed that he first sought medical attention in January, 1937, at which time he was admitted to the diagnostic clinic. His history at that time was of precordial pain of three years' duration brought on by exercise. This pain occurred about one to two times monthly; it lasted one to two minutes and was accompanied by dyspnea, palpitation, and weakness. He also gave some history of occasional frontal headaches, poor vision, and nocturia two to five times. He denied past illness, except for urethritis at the age of 28. At this time (January, 1937) his physical findings revealed the following positive features:

Eyes: Pupils equal, regular, and reacted to light and accommodation.
Mouth: Dental caries.

Chest: Resonant and clear throughout.

Heart: Enlarged, regular, good tone, precordial systolic bruit, aortic second sound accentuated.

Blood pressure: 220/120—Vessels moderately firm.

Abdomen: Negative except for a small left inguinal hernia.

Extremities: No edema—reflexes normal.

His Wassermann test was negative and his electrocardiogram showed an occasional extraventricular systole with slurring QRS. He was advised to return for further therapy but failed to do so. The next association with him was at the time of his present admission. When admitted, he appeared to be well developed and well nourished but seemed to be suffering much pain. He was breathing about thirty times per minute but showed no cyanosis. The positive findings were as follows:

Chest: Elliptical in shape. Expansion somewhat limited on the right side. Resonance was unimpaired. The breath sounds were somewhat suppressed in the right base, otherwise vesicular throughout. No râles were heard.

Heart: Enlarged to the left, regular in rate, good tone. Aortic second sound accentuated. Blood pressure 220/124.

Abdomen: Moved with respiration. There was resistance to palpation in the right upper quadrant. Tenderness was present throughout, more so in the gall bladder region. No organs or masses were felt.

Extremities: No edema.

The impression at the time of admission was (1) hypertension with myocardial hypertrophy and dilatation, (2) possible cardiovascular syphilis and aneurysm, and (3) possible surgical abdomen.

Because of the possibility of an acute abdomen, surgical consultation was obtained. In addition to the findings already mentioned, the patient was now complaining of hemoptysis and pain in the chest on deep inspiration. His urine was negative and his white blood cell count was 22,250, with 92 per cent polymorphonuclear cells. The possibilities entertained at this time were (1) perforated ulcer, (2) coronary thrombosis, and (3) acute pancreatitis.

While no definite diagnosis was made, it was thought advisable to observe the patient on the surgical service. Approximately six hours after his transfer to the surgical service, we again saw him. The pain was still present in the abdomen, and the cough, productive of bright blood, persisted. The temperature which was 97.2° F. on admission was now 101.2° F., and the pulse had become more rapid, 88 to 136. The blood pressure which had been 200/104 on admission was now 140/92 on the left arm, and 170/100 on the right arm. His physical findings at this time showed:

Chest: Marked diminution of breath sounds in the right base.

Heart: Enlarged, regular in rate, tones moderately suppressed, a "G" string type of pericardial friction rub was heard in the fifth interspace to the left of the sternum.

Abdomen: There were fullness and spasm with definite tenderness in the right upper quadrant. No masses were palpable.

Extremities: Slight cyanosis of the nails.

The impression at this time was possible coronary thrombosis or dissecting aneurysm.

An electrocardiogram was taken which revealed left axis deviation and myocardial damage. X-ray at this time showed an enlarged heart with the aorta normal. Therapy consisted of opium sedation, rest, and observation. X-ray was repeated on December 20, 1938, and the heart showed an increase in diameter of fully 4 cm. On December 30 fluid was present in the left pleural space, and thoracentesis was performed with the removal of 300 c.c. of straw-colored fluid which microscopically revealed red blood cells, some granular debris, some polymorphonuclear cells with a predominant small round cell element. Although his treatment was symptomatic, the patient did not respond and death occurred on January 11, 1939.

Post-Mortem Findings.—The left pleural cavity contained 1,400 c.c. of a rather thin, clear, yellowish-brown exudate. This contained numerous clots and fibrinous tags, composed of yellowish-green material. The lungs were dark slate gray in color, with a black over-mottling of anthracotic pigment. There were patchy areas where the lung was collapsed; these were firm on section and dark hemorrhagic in color. The parietal and visceral pleurae of the left side were fibrously thickened. Crepitation was present throughout both lungs. The cut surface was dark purplish red color and on compression oozed a large amount of sero-sanguineous frothy fluid. The lymph nodes at the hilus of the lung were enlarged and on section were black in color. The trachea-bronchial tree showed the mucous membrane covered with a marked amount of mucus.

Heart: The heart was markedly enlarged. The pericardium was adherent. On section through into the heart, a large, currant jellylike clot about the size of an orange, was found anterior to and somewhat to the right of the right ventricle in the pericardial space. This bulged considerably, making the heart appear large laterally. The aorta was split into two layers, this split extending to the base of the heart where the pericardium was attached around the aorta. There was a large amount of dark clotted blood between these layers. This space communicated with the large pericardial space filled with blood. The myocardium was of fair tone. The valves and valvular orifices were clear. The septum left ventricle beneath the cusps revealed subendocardial hemorrhage. The aorta showed numerous thickened areas of raised yellowish plaques. One of these communicated with the split space. The pulmonary arteries and veins were clear.

Abdomen: Abdominal viscera were essentially normal.

Anatomic Diagnosis.—Aortal arteriosclerosis with dissection between the coats and rupturing into a pericardial pocket, a space otherwise obliterated by fibrous adhesion, was found.

CONCLUSION

1. A dissecting aneurysm of the aorta, proved anatomically, has been presented.
2. The difficulty of clinical diagnosis is emphasized.

A NOTE ON *SACCHAROMYCES FRAGILIS* JORGENSEN ASSOCIATED WITH PATHOLOGIC CONDITIONS IN HUMAN BEINGS*

NORMAN CALLENDER LAFFER, PH.D., TUCSON, ARIZ.

SACCHAROMYCES FRAGILIS was first isolated by Jorgensen from kefir, and has repeatedly been found in dairy products. Within the last fifteen years, there have been two reports of the isolation of yeastlike fungi from pathologic conditions in human beings in which the organisms proved to be *Saccharomyces fragilis* Jorgensen. In both cases, the organisms were first classified as some other species, but upon detailed study at the Centraalbureau voor Schimmelteeltures at Baarn, Holland, they proved to be strains of *Saccharomyces fragilis*. In the first case, Redaelli in 1925 (Stelling-Dekker, 1931) reported the isolation of *Saccharomyces cavernicula* n. sp. from the lung of a tuberculous patient. Of this culture, Stelling-Dekker (1931) writes as follows: "A careful consideration of this species allows one to conclude that all major characteristics agree with those of *Saccharomyces fragilis* Jorgensen. The agreement is so definite that a separation of *Saccharomyces cavernicula* as a variety of *Saccharomyces fragilis* is not warranted. . . ." Another place she writes: "*Saccharomyces cavernicula* Redaelli is identical with *Saccharomyces fragilis* Jorgensen."

In 1935 Ciferri and Redaelli (Diddens and Lodder, 1939) described a species that had been isolated by Careo at Catania from a lesion of the human tonsils and pharynx. It was classified as *Monilia pinoyisimilis* (A. Castellani) Redaelli and Ciferri variety *Citelliana* Redaelli and Ciferri. Of this organism Diddens and Lodder (1939) write: "It evidently belongs to the genus *Saccharomyces* and it is completely identical with *Sacch. fragilis* Jorgensen."

The purpose of this article is to report an organism isolated by Miller (1935) and classified by him as *Monilia pseudotropicalis* Castellani. I secured a transfer of this strain and continued its study and found it to be identical with *Saccharomyces fragilis* Jorgensen (Laffer, 1936). Such results are not surprising for two reasons: first, the difficulty with which some strains are stimulated to produce ascospores; and second, the following statement by Diddens and Lodder (1939): "*Monilia pseudotropicalis* Castellani—*Candida pseudotropicalis* (Castellani) Basgal has to be considered as the imperfect stage of *Saccharomyces fragilis* Jorgensen." The material contained in the following paragraph is taken from the unpublished thesis of Miller (1935).†

Case history. The patient, a male, came to the physician with an acute infection of the tonsils, characterized by a sore throat, fever, malaise, anorexia, fetid breath, terribly coated tongue, headache, backache, and pains in the limbs. White or yellow patches of exudate were present in follicular form. Intensive treatment for follicular tonsillitis in the first seven

*From the Department of Bacteriology, University of Arizona, Tucson.
Received for publication, October 23, 1939.

†Published with the permission of Dr. Miller.

days did not show the slightest improvement. On the eighth day he was given 10,000 units of diphtheria antitoxin, and the dose was repeated on the ninth day; he recovered rapidly without further treatment. At no time were there objective signs of diphtheria.

According to Miller, his culture isolated from this case had the characteristic fermentative reactions of *Monilia pseudotropicalis* Castellani and serologic studies confirmed this relationship. When the unknown strain was used to produce an antiserum, the antiserum reacted with its specific antigen 1:640; with one type culture of *Monilia pseudotropicalis* 1:640; and with a second type culture of *Monilia pseudotropicalis* 1:320. Agglutinin absorption tests substantiated these serologic findings. The usual morphologic studies were not reported in the thesis. In his conclusions Miller stated: "Culture 10Y which produced acid and gas in dextrose, levulose, galactose, sucrose, raffinose lactose, and inulin, corresponds almost exactly to two cultures of *Monilia pseudotropicalis* Castellani (one from New Orleans, Louisiana, and the other from London, England) which fermented the same carbohydrates with acid and gas. These three cultures formed a distinct group by agglutinin absorption."

In my study (Laffer, 1936) of this culture (Miller's 10Y) the cells were characterized as "cells oval and rod shaped, but becoming filamentous in older broth cultures and potato broth, and producing rod shaped to filamentous asci and ovoid to kidney shaped ascospores." The culture produces one to four ascospores per ascus when grown on carrot blocks or on carrot infusion agar for three days or more at room temperature. Careful examination of colonies on malt extract agar (Difco) streak plates showed pseudomycelia penetrating the substrate, with the groupings of the blastospores at the junction of the adjoining elements similar to those produced by the control culture of *Saccharomyces fragilis* Jorgensen, obtained from the Lister Institute (their No. 2303). Cells grown in malt extract broth (Difco) for twenty-four hours were more or less rod-shaped and measured 3.0 to 5.0 microns by 6.0 to 10.0 microns, with a few filamentous cells as long as 12.0 to 21.0 microns. In older cultures the length and number of the filamentous cells increased.

The biochemical changes produced by the unknown and the control culture were the same, namely: acid and gas in glucose, fructose, galactose, mannose, lactose, and inulin; acid and no gas in raffinose, and neither acid nor gas in arabinose, xylose, rhamnose, maltose, salicin, glycerol, mannitol, dextrin, and starch. For these determinations, nutrient broth base (Difco) plus 1 per cent carbohydrate and bromocresol purple was used. Litmus milk, if incubated at room temperature, became acid with evidence of gas production after a few days, but if incubated at 37° C., the milk was curdled with a renninlike curd. There was no evidence of proteolysis at the end of forty-five days of incubation. When tested by the Hammer and Collins (1935) method, the organism did not hydrolyze fat. No true liquefaction of gelatin was observed at 37° C. after forty-five days of incubation, while "softening" occurred in those cultures incubated at 18° C. to 25° C. for forty-two days. An uninoculated control showed no "softening." The term "softening" is used to indicate a stage in which the medium is soft at room temperature but the gelatin becomes solid upon cooling to 5° C. to 8° C. This term is used in contrast to true liquefaction in

which the medium fails to solidify upon cooling to the above temperatures. While Stelling-Dekker reports that *Saccharomyces fragilis* liquefies gelatin, a difference in the composition of the medium may account for the variation in the degree of utilization of the substrate.

SUMMARY

1. A third case in which *Saccharomyces fragilis* Jorgensen has been isolated from a pathologic condition in human beings is reported.

2. Confirmation of the relationship of *Saccharomyces fragilis* Jorgensen and *Candida* (Monilia) *pseudotropicalis* (Castellani) Basgal, as indicated by Diddens and Lodder (1939), is implied.

3. The desirability of an attempt to further confirm this relationship by serologic studies is suggested.

4. While nothing is contained to indicate that *Saccharomyces fragilis* is the causal agent in the infections of the throat, the finding of this species in throat cultures might prove worthy of a more detailed investigation or might prove to be a lead worthy of following. Careful morphologic studies of yeasts found, including repeated attempts at ascospore determination, and the inoculation of lactose, sucrose, inulin, maltose, litmus milk, and gelatin, would probably suffice for preliminary study and tentative identification.

The wide distribution of this organism is clearly shown. I have found this species in cream obtained in Illinois, and have identified as *Saccharomyces fragilis* cultures received from S. Orla-Jensen, Copenhagen, Denmark (from milk); from the late Dr. Henneberg, Kiel, Germany (from yoghurt); from W. Dorner, Liebefeld-Berne, Switzerland (from sour milk and whey); and from Erivan, Armenia, U. S. S. R. (from matzoon). It is easy to see how such organisms could get into the throat and thus be found in examination of throat cultures.

THE ACTION OF EPINEPHRINE INJECTED INTO THE PERICARDIAL SAC*

PHILIP BLICKENDORFER, PH.D., AND J. A. BONE, M.S., M.D.
CHICAGO, ILL.

WHILE the effect of epinephrine on blood pressure when given intravenously has been widely studied, the effect when given by other routes has not received adequate attention. When given by oral administration, it is usually inactive in normal people. Menninger¹ studied the effect of oral administration in various types of hyperthyroid cases. He gave the patients from 2 to 5 mg. of epinephrine in gelatin capsules and concluded that in some cases epinephrine may produce a marked effect on the circulation with rise of pressure. The effect results from absorption through the gastrointestinal tract and not from the mouth or throat.

Meltzer and Auer² found that the subcutaneous injection of 0.4 to 0.5 c.c. per kilogram of epinephrine has no influence on the blood pressure of a rabbit. Intraperitoneal injection also has no effect on the blood pressure, while 0.3 to 0.4 c.c. given intramuscularly may produce a rise of 40 to 50 mm. The rise is not so sudden as it is after intravenous injection.

Amberg³ previously reported that doses of epinephrine that are fatal when given intravenously do not exert pressor effects in cats, dogs, or rabbits when given subcutaneously, although a very large dose (37 mg. per kilogram) raises the blood pressure in the dog.

Halsey⁴ found that 27 mg. of epinephrine given intramuscularly to a 14 kg. dog raised the pressure 30 mm. (from 140 to 170). In man he found that the oral administration of epinephrine does not change the heart action or blood pressure; when subcutaneously administered, a dose of 0.5 to 1.5 mg., or about 0.5 to 1.5 c.c. of 1:1,000 solution, is uncertain in its effects on the blood pressure but usually causes a slight rise. This same dose, however, given intramuscularly may cause alarming symptoms and a rise of pressure of 90 mm. (110 to over 200). Since some people are sensitive to epinephrine, Halsey recommends that smaller doses be given until the reaction is known.

Grollman⁵ quotes Euler and Liljestrand as having found that the subcutaneous injection of 0.7 mg. of epinephrine in man raised the blood pressure 17 mm. and increased the cardiac output from 4.3 liters to 7.5 liters per minute; this indicated both stimulation of cardiac activity and diminished peripheral resistance.

*From the Department of Pharmacology and Therapeutics, University of Illinois College of Medicine, Chicago.

Received for publication, November 1, 1939.

Auer and Gates⁶ found that when 0.25 c.c. of epinephrine solution (1:1,000) per kilogram is given intratracheally in rabbits, a rise of pressure occurs after a few seconds and lasts for about five minutes. Jackson⁷ records similar findings. We have found similar results to follow injection into the pericardial sac of dogs (see Figs. 1 and 2).

Fig. 1.—The effect of 10 c.c. epinephrine, 1:25,000, in the pericardial sac. (Dog—19 kg.)

Fig. 2.—The comparative effect on blood pressure of 1 c.c. epinephrine, 1:25,000, intravenously and intrapericardially. The rapid rise in this case after intrapericardial injection is unusual.

METHOD

Dogs were anesthetized with 35 mg. per kilogram of pentobarbital in solution, given intraperitoneally. Blood pressure was recorded from the carotid artery. Artificial respiration was used throughout. The chest was opened and the solution of epinephrine placed in the pericardial sac so that none was lost

by leakage. Duodenal activity was recorded by the balloon method. The tracings show the effect. After and before injection into the pericardial sac, an injection was made into the saphenous vein in order to compare the relative effects of adrenalin when given intrapericardially and intravenously.

CONCLUSIONS

1. The effect of epinephrine injected into the pericardial sac is less abrupt but prolonged about five times as compared to the intravenous injection. About five to ten times the intravenous dose is necessary to produce identical rise in blood pressure.

2. The intrapericardial action of epinephrine in smaller doses is somewhat irregular on the blood pressure but is very constant on the intestines.

TORULA INFECTION OF THE CENTRAL NERVOUS SYSTEM*

A REPORT OF A CASE WITH NECROPSY FINDINGS

LEON H. GOLDBERG, M.D., NYACK, N. Y.

SINCE 1907 sporadic reports of torula infection have appeared in the literature. By far the most comprehensive monograph on the subject was presented by Stoddard and Cutler in 1916. In view of the frequency with which this infection is being reported, it is noteworthy to quote verbatim Stoddard's memorandum in 1916: "It would not have been too venturesome to have prophesied that the organism would be found at some future date producing nervous diseases in man. It will take time to determine how common this type of infection is, but many facts indicate the possibility of it being frequently present without recognition."

In 1939 McGrauder published protocols of 3 cases observed at the University of Virginia Hospital since October, 1935, in which he succeeded in isolating the organism. In a personal communication he submitted the following outline:

1. The technician who examines the spinal fluid must be torula conscious.
 2. Identify as a yeast (as contrasted with cells) in the counting chamber.
- The count is made as usual with acetic acid to lake any red blood cells present.

*From the Medical Service, Nyack Hospital.
Received for publication, October 28, 1939.

Torulae might be mistaken for lymphocytes (and usually are) unless one has the probability of torula in mind. The torula organism will show some budding forms, and a thick wall, often surrounded by a definite capsule. No cytoplasm is seen.

3. If torula is suspected, mix a drop of sediment (from centrifuged spinal fluid) with a drop of Greenthal's stain on a slide, cover with a cover glass and examine. The stain will show definitely the nuclei and cytoplasm of the usual cells, distinguishing them clearly from the torulae, which show a definite "cellulose-like" wall, surrounded by a wide purplish or bluish capsule.

4. Confirm by culture. *Torula* usually reproduces by budding only, never forming mycelium, and does not ferment sugar.

It becomes evident that the apparent increase in reported cases is not necessarily an indication of an increased frequency of the infection in man, but rather an indication of an increased interest in the problem with a concurrent improvement in laboratory diagnosis.

The following case report, with its autopsy findings, is as typical of the vagaries of this infection as other cases reported to date.

CASE REPORT

A colored girl, aged 19 years, was first seen on March 3, 1938. She was prostrated, complained of an intractable headache of several weeks' duration, and had photophobia. The examination revealed a marked nuchal rigidity as the only positive sign of any cranial involvement. Ordinary palliative measures were of no avail. After three days, a spinal tap was done for diagnostic purposes as the picture suggested tuberculous meningitis. For the next three days there was no relief. On the assumption that it might be tuberculous meningitis, notwithstanding the negative findings in the spinal fluid, she was placed on a high vitamin D intake, and to my amazement she began to improve almost immediately. She returned to normal activity in two weeks.

Five months later the girl again became ill. In the early days of this recurrence, the picture was identical with that originally presented. This time, however, a series of neurologic signs appeared, following one another in rapid succession. On August 11 she lay in bed in a stupor, with her head and eyes sharply deviated to the right, while the right arm and leg were flaccid. The left hand constantly clutched at the bedclothes. The abdominal reflexes were absent. Both pupils reacted very sluggishly, and the right one was smaller than the left. There were reddening of the fundi, with engorgement of the veins. The jaw was tonically closed. There were positive Brudzinski and bilateral Hoffman signs. The following morning the patient was still in coma. The right limbs remained flaccid and both ankles showed clonus. Her temperature rose to 106° F.; her pulse rate increased to 140 and her respiratory rate remained between 20 and 30. On August 13 she died.

Her skin was dry and cool. Her heart, lungs, and abdomen were essentially negative. Neurologically, she continued to present a continually changing picture with such signs as positive Babinski on the right side and negative Babinski on the left. All four extremities were stiff and spastic. She moved the left side involuntarily but not the right side. The pupils reacted slug-

gishly; the veins dilated to twice the normal caliber. No diagnosis was made, although the usual series of differential diagnoses presented themselves with cerebral abscess as the most likely process.

Spinal Fluid Findings.—August 11, clear, under moderate pressure; cell count, zero; chlorides, 330 mg. per 100 c.c.; glucose, 10 mg. per 100 c.c.; smear lymphocytes, 2; tubercle bacilli, negative; Wassermann, negative; culture, negative. August 13, cell count, polymorphonuclears, 11, lymphocytes, 89; protein, 96; globulin, 2 plus; sugar, 31 mg. per 100 c.c.; chlorides, 715 mg. per 100 c.c.; colloidal gold sol, 1111233100; Wassermann, negative.

Necropsy Findings.—An autopsy was performed soon after death. The brain was examined by the Department of Pathology of the Neurological Institute. The skull was of normal thickness. The dura was moderately adherent to the inner surface of the skull. The brain weighed 1,300 Gm. At the base of the brain, in the interpeduncular fossa, on the inferior surface of the hypothalamus and about the optic chiasm and nerves, the leptomeninges were thickened and grayish with an accumulation of yellowish-gray exudate. On section of the cerebrum, no gross lesions of the parenchyma were noted. The spinal cord leptomeningeal blood vessels were congested, but otherwise the cord appeared normal.

Microscopic examination of the area revealed a proliferation of leptomeningeal cells in the form of fibroblasts. There was a heavy infiltration of the membrane by lymphocytes, monocytes, and plasma cells. There were numerous multinucleated giant cells about focal areas of necrosis.

In places in the necrotic areas, there were pale, translucent, round bodies, with double refractive margins. No structural details could be made out within them; they varied in size from that of lymphocytes to that of monocytes. Some of these bodies were also found within the giant cells. These proved to be *Torula histolytica*. There were also a terminal lobular pneumonia and acute ulceration of the duodenum.

CONCLUSION

A case with necropsy findings of *Torula histolytica* infection of the central nervous system is presented.

CUTANEOUS HYPERSENSITIVITY TO IODINE*

JOHN L. JACOBS, M.D., AND ABRAHAM COLMES, M.D.
BOSTON, MASS.

THE occurrence in certain individuals of a local or contact dermatitis following the application of iodine has been described by many authors. Some^{1,4} speak of the symptoms as toxic in origin; others⁵⁻¹² consider them as manifestations of hypersensitiveness; and two authors¹³ do not indicate their opinion. Except for one instance⁷ of a patient giving a delayed reaction by scratch test to Lugol's solution diluted 1:16 (and not to 10 per cent potassium iodide), confirmatory skin tests have not come to our attention.

Most of the reports on iodine dermatitis are based upon single observations; this indicates the infrequent occurrence of this condition.

Recently a medical student, hypersensitive to iodine, became available for study. It seemed desirable, therefore, to investigate his abnormal reactivity in some detail.

CASE HISTORY

The subject for study, to be referred to hereafter as J. A. B., had no past history of allergy. Family history included a maternal aunt with asthma and a father suffering from migraine. Five years previous (at the age of 18) the patient first noticed dermatitis following application of tincture of iodine. Not long before that he had fallen on a cinder track, and his injury had been treated by a local application of tincture of iodine over a large area on his leg. Since then the application of iodine tincture has regularly caused a local dermatitis confined to the area exposed.

EXPERIMENTAL

A preliminary test confirmed the fact that tincture of iodine (7 per cent iodine, 5 per cent potassium iodide), which gives no reaction on normal controls, produced reddening in our patient within seven hours after the application of one drop to the skin. By the second day blisters had developed, with thickening of the epidermis. These blisters exudated serum for approximately two days and then began to dry up. The site of application could be detected for some time; after a month it was still slightly reddened and covered with scabby scales. A 1:10 dilution of the above tincture in alcohol also produced a similar reaction, though of lesser intensity.

Another series of tests was performed on this patient with a tenth normal iodine solution (1.3 Gm. iodine and 3.0 Gm. potassium iodide in 100 c.c.). Tenth normal iodine solution does not irritate the skin of normal individuals, but in

*From the Departments of Pathology and Bacteriology, and Medicine, Tufts College Medical School, Boston.

Received for publication, November 1, 1939.

This investigation was aided by a grant from the Charlton Research Fund of the Tufts College Medical School.

this patient it caused a reaction which was, however, less marked than that elicited by the iodine tincture. A few slightly raised, pale pink papules were present at twenty-four hours; they continued to increase in number and intensity of coloring so that after forty-eight hours the whole area affected was covered with pinkish elevations. A 1:10 dilution of tenth normal iodine solution failed to produce a reaction.

Powdered potassium iodide and a 1:1 solution of potassium iodide in distilled water failed to give a positive patch test. On the other hand, 0.5 per cent iodine salve in vaseline (crystals finely ground and mixed with vaseline in a mortar) which contained no potassium iodide, produced a marked delayed reaction. These results are tabulated in Table I.

TABLE I
SENSITIZATION TO IODINE

All recorded readings were made on the day following the test. In the patch tests an amount was used equivalent to the bulk of a pea; in the intracutaneous tests 0.02 c.c. was injected. Figures refer to millimeters.

TYPE OF TEST	SUBJECT	TEST PERFORMED WITH:			
		0.5% IODINE IN VASELINE	TINCTURE: 7% IODINE WITH 5% POTASSIUM IODIDE	5% IODINE IN ALCOHOL	SATURATED POTASSIUM IODIDE SOLUTION
Patch	J. A. B.	Pink, elevated	Pale pink, slightly elevated, spotty; 2 small vesicles	Negative	Negative
	Control 1	Negative	Negative	Negative	Negative
	Control 2	Negative	Negative	Negative	Negative
TYPE OF TEST	SUBJECT	TESTED WITH:			
		IODINE, 1:1,000, IN SALINE	IODINE, 1:10,000, IN 0.9% POTASSIUM IODIDE	POTASSIUM IODIDE, 1:100	DIODOTYROSINE 1:200
Intra-cutaneous	J. A. B.	4, pale pink slightly elevated	Negative	Negative	Negative
	Control 1	3, pale pink spot	Negative	Negative	Negative
	Control 2	3, faintly pink faintly elevated	Negative	Negative	Negative

When a vaseline salve containing only 0.25 per cent iodine was applied, no reaction occurred, whereas a 1.0 per cent salve, similarly prepared, caused irritation to normal skin. An attempt was made to increase this limited range of practicable ointment concentrations by the use of a method previously described for poison ivy hypersensitiveness in guinea pigs.¹⁴ In this technique a high concentration of the test substance is applied, being removed after a short time by a suitable agent. To this end a 5.0 per cent ointment of iodine in vaseline, carefully ground and otherwise prepared as above, was applied to the forearm of our patient and washed off after twenty to thirty minutes with soap and water, followed by tenth normal sodium thiosulfate solution. The test was read the next day. Controls were uniformly negative, whereas J. A. B. showed a marked reaction of the type described above (Table III). With the above technique, ointment concentrations up to 10.0 per cent iodine may be used. In this way differences between the sensitized individual and normal controls were made more striking.

In contrast to the markedly positive patch tests to iodine salve, intracutaneous tests on J.A.B (0.02 c.c.) with a 1:1,000 solution of iodine were essentially negative. It should be pointed out, however, that this concentration of iodine is slightly less than the weakest solutions capable of giving a patch test in this individual. An intracutaneous test with 1.0 per cent potassium iodide was likewise negative.

In order to gain further information concerning the mechanism of these reactions, it seemed important to study the response of J. A. B. to iodinated protein, since a positive reaction would indicate that the iodine had combined with protein in the body to form an antigen containing the specific group of iodoproteins, diiodotyrosine. It is known that this reaction can easily take place under these conditions,¹⁵ and reactions to formolized proteins in an individual hypersensitive to formaldehyde have been reported by Horsfall.¹⁶ Accordingly, several preparations of iodinated human serum were made by Wormall's method,¹⁷ and various tests were carried out on this patient and on suitable controls. A typical protocol is given in Table II.

TABLE II
TESTS WITH IODINATED PROTEIN

The readings are after fifteen minutes for the immediate reactions and after twenty-four hours for all others. Dilutions were made in saline and are expressed in terms of dry solids. Human serum was used in all the serum preparations. Measurements are in terms of millimeters.

SUBJECT	INTRACUTANEOUS TESTS WITH IODINATED SERUM				PATCH TESTS WITH:	
	0.05%		1.0%		PRECIPITATED IODINATED SERUM (WET SOLID)	DIIODOTYROSINE POWDER
	IMMEDIATE	DELAYED	IMMEDIATE	DELAYED		
J. A. B.	Wheal 8 Flare 19	8, pale pink, slightly elevated	Wheal 12 Flare 50	45, faintly pink, slightly thickened	Negative	Negative
Control 1	Wheal 9 Flare 20	3, pale pink spot	Wheal 11 Flare 50	30, faintly pink, faintly thickened	Negative	Negative
Control 2	Wheal 8 Flare 20	4, faintly pink	Wheal 7 Flare 40	35, very faint- ly pink, no thickening	Negative	Negative

It will be noted that, as far as immediate reactions are concerned, no marked differences were noted between J. A. B. and the controls. This is interesting because strongly positive reactions would be expected in human hypersensitivity to iodinated protein. Such differences in delayed reactions as occurred may not have been enough to be significant. While these tests were being carried out, it happened that another individual, J. B. H., hypersensitive to formaldehyde, was available. J. B. H. was tested for hypersensitivity to formalized human serum, but, as in the above instance with iodinated proteins, the outcome was essentially negative.

Failure of patch tests with precipitated iodinated protein, and diiodotyrosine, the specific grouping in iodinated proteins, was quite definite. Intracutaneous tests with diiodotyrosine were likewise negative (Table I). No generalized reaction was observed following any of the tests, although local reactions from

the patch tests at times were exceedingly severe. The responses observed were exclusively of the delayed type.

Since hypersensitiveness is a highly selective phenomenon, it was of interest to learn whether idiosyncrasy to iodine is subject to the same law of specificity. To obtain this information cross tests were performed with iodine and formaldehyde on J. A. B. and J. B. II. The method of testing and results noted are given in Table III.

TABLE III
SPECIFICITY OF IDIOSYNCRASY TO IODINE
Readings made on the day following the test

SUBJECT	TESTED WITH:		
	5% IODINE IN VASELINE WASHED OFF AFTER 15 MINUTES WITH SODIUM THIOSULFATE	LANOLIN SALVE CONTAIN- ING 10% FORMALDEHYDE —NOT WASHED OFF	LANOLIN—NOT WASHED OFF
J. A. B.	Pale pink, slight vesiculation	Negative	Negative
J. B. H.	Negative	Pink, thickened, and rough	Negative
Control 1	Negative	Negative	Negative
Control 2	Negative	Negative	Negative

It will be observed that with these two substances, iodine and formaldehyde, the specificity was definite. J. A. B., hypersensitive to iodine, had a pink, slightly vesiculated lesion twenty-four hours after treatment with iodine salve, but gave no trace of reaction with formaldehyde salve. In J. B. II. the opposite reactions were observed. Thus these idiosyncrasies appear to be as specific as other immunologic phenomena. Since hypersensitivity to lanolin has been reported, a control test of this substance was included.

DISCUSSION

Interpretation of these studies is necessarily limited by the fact that they were obtained from a single experimental subject. However, certain points seem to be clear. The condition known as contact sensitivity to iodine is a manifestation of hypersensitiveness and is characterized by strict specificity. All intracutaneous tests with iodine solutions or iodinated protein were negative or equivocal.

In regard to the failure to obtain immediate reactions to intraeutaneous injections of iodinated protein, it should be considered that a single negative result of this sort does not carry much weight. However, the tests were repeated a number of times with different preparations and concentrations, and the opportunity for technical errors would not seem to be great. It would seem that Wolff-Eisner's hypothesis¹⁸ that these idiosyncrasies are due to the formation of an antigen by the combination of iodine with body constituents has not yet been proved. It may be recalled, however, that reactions with protein combinations have been obtained in guinea pigs¹⁹ sensitized to simple chemical substances.

The absence, noted in Table I, of a dermal reaction to a simple alcoholic solution of iodine (no potassium iodide) was observed twice but needs further confirmation since tests were performed with a minimal quantity of material in an attempt to avoid unnecessary reactions in this very hypersensitive patient.

SUMMARY

An individual giving marked contact reactions with iodine was examined. The specificity of the reaction and methods of testing were studied. Intradermal tests were essentially negative. No conclusive evidence of sensitivity to potassium iodide, diiodotyrosine, or iodinated protein was observed.

ACUTE ENDOCARDITIS DUE TO AN ANAEROBIC PNEUMOCOCCUS*

ALVIN HOLLANDER, M.S., AND EVA LANDSBERG, M.D.
BROOKLYN, N. Y.

IN 1936 three strains of anaerobic pneumococci were described by Smith.¹ Of these, two different strains were isolated from the throat of a patient with chronic bronchitis and one was obtained by post-mortem culture from the lung in a patient with pneumonia. White² cites a personal communication from Avery regarding the occurrence of anaerobic pneumococci. We have not been able to find any other descriptions of anaerobic pneumococci. The following case is the first instance in which such organisms have been isolated from the blood stream during life and also the first case of acute endocarditis caused by an anaerobic pneumococcus.

REPORT OF CASE

D. L. (Hospital No. 221450), a 9-year-old boy, was admitted to the Pediatric Service on April 22, 1939, with the following history: Thirteen days prior to admission, he complained of a headache on the left side of his head. Daily fluctuations in temperature from 98.6° to 104° F. were observed. On the third day of his illness, there developed swelling and redness of the left eye, and pain in the neck without rigidity. Eight days before admission, a cardiac murmur was heard for the first time by the family physician. During the three days before admission four chills occurred, with temperature elevations reaching 105.2° F.

Physical Examination: The patient was well nourished, well developed, and acutely ill. There was injection of the nose and pharynx and slight enlargement of the cervical lymph nodes. The heart was not enlarged but there was present a high-pitched musical systolic murmur at the apex, transmitted to the axilla. The spleen was palpable 0.5 cm. below the costal margin and was firm but not tender. The liver was palpable 1.5 cm. below the costal margin. The swelling of the eye was no longer evident and the pains in the neck had disappeared. The laboratory data were as follows: hemoglobin 70 per cent, erythrocytes 3,570,000 per cmm., leucocytes 12,500 per cmm., with 82 per cent polymorphonuclear cells, of which 23 per cent were band forms, 14 per cent lymphocytes, and 4 per cent monocytes. The urine was negative.

Course: At 10:00 p.m. on the day of admission the patient had a chill with a rise of temperature to 105° F. A blood culture taken at this time showed a growth of anaerobic pneumococci after three days (the organisms will be described later). On the following day there developed a slight swelling and tenderness of the left knee and left shoulder and hip.

On April 24, two days after admission, the patient showed signs of meningitis with rigidity of the entire spine and neck. The Kernig sign could not be evaluated because of the pain in the left limb. Lumbar puncture revealed a turbid spinal fluid under slightly increased pressure. A cell count of 1020 per cmm., with 93 per cent polymorphonuclear cells and 7 per cent lymphocytes was obtained. The sugar content was normal. A Gram stain of the fluid showed very rare gram-positive diplococci which failed to grow on culture. Blood culture revealed the same organism previously isolated.

Because of the presence of gram-positive cocci in the spinal fluid, intrathecal sulfanilamide and oral sulfapyridine therapy were instituted. Spinal fluid withdrawn immediately before the first intrathecal injection of sulfanilamide contained 760 cells per cmm., 75 per cent being polymorphonuclear cells and 25 per cent lymphocytes. This specimen showed no organisms in the direct smear and no growth on culture.

*From the Division of Bacteriology, Departments of Laboratories and Pediatrics, the Jewish Hospital of Brooklyn.

Received for publication, November 3, 1939.

By the next morning the temperature had dropped to below 100° F. The tenderness in the lumbosacral region and left leg and the nuchal rigidity had almost completely disappeared. Roentgenographic examination of the hip and pelvis was negative. There was present definite haziness in the left frontal, ethmoidal, and maxillary sinuses. (Cultures were not obtained directly from the sinuses, but nose and throat cultures showed no anaerobic pneumococci.) During the next week the temperature remained below 100° F. and the child's condition appeared to improve.

On May 2 a tender erythematous area, 3 cm. in diameter, was seen on the dorsum of the right foot. On May 4 and May 6 the patient had chills with a positive and negative blood culture, respectively. On the latter date he complained of severe pain in the left hand which showed tenderness and swelling of the metacarpal region and redness and swelling of its volar surface. In the evening of the same day a purpuric rash appeared on the volar surfaces of both hands and the plantar surface of the right foot. The rash consisted of reddish-violet spots, about 0.5 cm. in diameter, which were not elevated and which faded on pressure. Cultures of these areas were negative. The spleen was palpable 3 cm. below the costal margin and was hard, firm, and not tender. The fundi were normal. By May 14 the rash was almost gone. The patient had a yellowish pallor but no jaundice. There was pain in the right elbow which, however, was not red or swollen. The murmur was much louder and scattered sibilant râles were heard over both lung fields. The liver could now be felt 4 cm. below the costal margin.

On May 16 the face was flushed and had a cyanotic tinge. There was present in each eye a hemorrhage at the margin between the inferior bulbar and palpebral conjunctivae. On May 20 the patient became irrational and delirious. Convulsive seizures occurred, starting on the left side and becoming generalized in a few seconds. During these seizures the right arm and leg were spastic. The course continued steadily downhill and the patient died on May 22. A lumbar puncture shortly before death showed a turbid fluid with innumerable gram-positive diplococci. On culture these organisms proved to be identical with those isolated from the blood. Consent for autopsy was not given.

BACTERIOLOGIC STUDIES

The organism was a small gram-positive lancet-shaped diplococcus which could be grown only under anaerobic conditions. The colonies, like those of pneumococci, were flat and surrounded by an area of greenish discoloration. It was bile soluble but did not give a "Quellung" reaction with the sera of the known types. Fermentation with acid and clot formation occurred in inulin, galactose, lactose, maltose, saccharose, mannite, sorbitol, dextrose, salicin, glycerol, and levulose serum media. The strain isolated by Smith differed in that no reaction took place in mannite, and acid only was formed in sorbitol and glycerol.

Per se the organism was not pathogenic for mice. When injected together with mucin, however, the mice were killed in eighteen hours by a suspension containing 150,000,000 organisms per cubic millimeter and positive cultures were obtained from the peritoneal exudate and heart's blood. In rabbits the intravenous injection of as much as 2 c.mm. of an eighteen-hour broth culture caused a transient bacteremia which did not have a fatal outcome. When the animals were sacrificed six weeks after the injection, the only lesions present were a few small abscesses in the liver. Intraentaneous inoculation of 1 c.mm. produced the same picture except for the presence of a huge local abscess around the site of the injection. Guinea pigs were killed by the intraperitoneal injection of 1 c.mm. of an eighteen-hour broth culture, although 0.1 c.mm. was not fatal.

Mice infected with the organism-mucin mixture were not protected by either sulfapyridine or sulfanilamide. Control experiments with a virulent pneumococcus revealed that mice could not be protected against suspensions of the same density, although the therapy was effective against smaller numbers of lethal doses. Obviously, no conclusion can be drawn concerning the susceptibility of our strain to sulfapyridine.

Rabbits were immunized by repeated intravenous injections of a suspension of killed organisms. The antiserum produced gave positive "Quellung," agglutination, and protection tests with the homologous strain. No "Quellung" reaction was obtained with any of the 32 known serologic strains, and agglutination and protection tests with types I, II, V, VI, and XIV were negative.

For approximately four months after its isolation, the organisms could be grown only under anaerobic conditions. After this period, however, it began to grow aerobically. At first there was a scanty growth but within five days it grew luxuriantly. The aerobic strain was identical with the anaerobic in its fermentation and serologic reactions, its virulence for mice, and its behavior to sulfapyridine.

DISCUSSION

A case of acute endocarditis and meningitis caused by an anaerobic pneumococcus is reported. The onset with headache and swelling of the eye and the roentgenographic evidence of infection in the sinuses indicate that these were the primary foci, although in the absence of positive cultures this cannot be stated definitely.

Since soluble sulfapyridine was not then available, intrathecal sulfanilamide was given and maintained at a level of 7.6 mg. per cent for five days. The effect of this therapy is difficult to evaluate. As seen from Table I, the second spinal fluid was already sterile and the number of cells had fallen from 1,020 to 760 per cubic millimeter. The subsequent fluids, except for the last one, were all sterile and showed a steady decrease in the cell count. The intrathecal therapy was discontinued when the number of cells had fallen to 29.

Concurrently with the intrathecal sulfanilamide, oral sulfapyridine was instituted. On April 26, two days later, a blood level of 15 mg. per cent was reached. During the next week a total of 725 grains of sulfapyridine was given. The temperature in this period was below 100° F. On May 4 the patient suffered a chill with a rise in temperature to 104.2° F. A blood culture at this time was positive. The concentration of sulfapyridine in the blood which had been 9.4 mg. per cent the previous day had fallen to 5.7 mg. per cent. The spinal fluid showed no organisms and had only 21 cells per cubic millimeter. Since the temperature remained high and the blood sulfapyridine could not be raised above 6.9 mg. per cent by oral administration, a soluble sulfapyridine compound (7 per cent solution) was given intravenously. After two intravenous injections the temperature curve appeared to take a downward trend. On the next day, despite a sulfapyridine level of 11.1 mg. per cent, a positive blood culture was obtained. For the next two days the temperature ranged between 99° and 101° F. Following the third injection, however, a rise in temperature occurred and the intravenous therapy was dis-

TABLE I
SPINAL FLUIDS

DATE	PRESSURE	APPEARANCE	SMEAR	CULTURE	CELLS	SULFAPYRIDINE CONCENTRATION (MG. %)
4/24	Slight increase	Turbid	Gram-positive diplococci (rare)	No growth	1,020 (93% polys.) (70% lymph.)	
4/25	Slight increase	Turbid	No organisms	Sterile	760 (75% polys.) (25% lymph.)	5.0
4/26	Slight increase	Turbid	No organisms	Sterile	860 (69% polys.) (31% lymph.)	6.5
4/27	Slight increase	Clear	No organisms	Sterile	220 (79% polys.) (21% lymph.)	7.9
4/28	Normal	Clear	No organisms	Sterile	96 (80% polys.) (20% lymph.)	8.4
4/29	Normal	Clear	No organisms	Sterile	70 (52% polys.) (48% lymph.)	7.8
4/30	Normal	Clear	No organisms	Sterile	29 (62% polys.) (38% lymph.)	8.4
5/ 1	Normal	Clear	No organisms	Sterile	32 (37% polys.) (63% lymph.)	
5/ 4	Slight increase	Clear	No organisms	Sterile	21 (48% polys.) (52% lymph.)	
5/22	Slight increase	Turbid	Innumerable gram-positive diplococci	Anaerobic pneumococcus		

TABLE II
BLOOD

DATE	CULTURE	SULFAPYRIDINE CONCENTRATION (MG. %)
4/22	Anaerobic pneumococcus	
4/24	Anaerobic pneumococcus	
4/26		15.0
5/ 3		9.4
5/ 4	Anaerobic pneumococcus	5.7
5/ 6	Sterile	
5/ 9	Sterile	6.9
5/11	Anaerobic pneumococcus	11.1
5/18	Anaerobic pneumococcus	3.2

continued. The patient continued to receive 60 grains of sulfapyridine daily by mouth. Nevertheless, one week later the blood level was only 3.2 mg. per cent. From Table II it is obvious that there was no relationship between the outcome of the cultures and the concentration of sulfapyridine in the blood. This fact was given added support by our experiment which showed the resistance of the organism to the drug.

Data concerning the frequency of the occurrence of anaerobic pneumococci is not available, since they are, as a rule, not sought for routinely. Our observations suggest that further investigation along these lines is needed.

SUMMARY

1. A case of acute endocarditis and meningitis caused by an anaerobic pneumococcus of a new serologic type is reported.

2. The identity of the organism was established by its solubility in bile, fermentation of inulin, and "Quellung" reaction with an homologous immune serum.

3. These organisms were not pathogenic for mice, which could be killed by the injection of a heavy suspension in mucus.

4. Mice infected with mucus suspensions of these organisms were not protected by either sulfanilamide or sulfapyridine.

We wish to express our gratitude to Mrs. Anita Rosenfeld for her technical assistance.

ADDENDUM: In a recent article Walter and her co-workers¹ described a new type of pneumococcus which they designated as type 33. Miss Walter was kind enough to examine our strain and found it to be of the same type.

A QUALITATIVE AND QUANTITATIVE STUDY OF ATMOSPHERIC POLLEN AT MOSCOW, IDAHO

JEAN B. DAUBENMIRE, M.S., MOSCOW, IDAHO

THE collections of atmospheric pollen grains used in this study were obtained by exposing gelatin-coated microscope slides on top of Morrill Hall on the campus of the University of Idaho at Moscow. The campus is on a hill, and the roof of Morrill Hall, a four-story building, is high enough that the local vegetation has a minimum effect upon the composition of the pollen of the atmosphere.

An attempt was made to collect pollen for every twenty-four-hour period. This was not always possible, and as many as six days elapsed between some of the samples.

The slides were prepared according to Wodehouse's¹ glycerin jelly method, and the stain, basic fuchsin, was prepared according to the method of Chamberlain.² The slides were exposed 6 inches below the flat roof of a small especially constructed shelter. After exposure the slides were stored in cream sample bottles to keep them from gathering more pollen and dust before the cover slips were applied. They could be stored in this way indefinitely if rainy weather did not excessively moisten the gelatin so as to permit mold spores to germinate.

Wodehouse's¹ key for the identification of pollen grains was used, and as further aids in identification, observations were made on the phenology of plants in the Moscow vicinity, and reference mounts were prepared from fresh or from herbarium specimens.

Slides were exposed from February 19 until December 2, although no pollen was found on them before March 5 or after November 30.

The first pollen caught was three grains of grass pollen which appeared on March 5 (see Chart 1). Since no other grains of this type were caught until late in April, these grains were apparently produced the previous year. Other pollens appearing too early for the regular seasons were from *Pinus*, *Artemisia*, *Chenopodiaceae*, or *Amaranthaceae*, and of the *Anthemis* and *Rumex* types. Pine sheds its pollen most abundantly in June, but old staminate cones were found shedding pollen in midwinter of 1939 shortly after this study was discontinued. This indicates a possible source of at least some of the stray grains collected out of the normal season. Duke and Durham³ state that rain washes from the pollen grains the active principle causing allergy, so that these few out-of-season grains can be completely ignored in using the data in the treatment of pollinosis.

Chart 1.—Pollen types collected at Moscow during 1938. Shaded area indicates the total span of the pollination season; black area indicates the interval between the first and last days on which five or more grains fell on the sample area of gelatin (3.24 cm.).

Although pollen analysts in other regions have distinguished between species belonging to the *Chenopodiaceae* and *Amaranthaceae*, this distinction was found impossible at Moscow. Table I, showing the measurements of a series of grains collected in early summer, indicates the difficulty encountered.

The local flora includes about twenty species in the *Chenopodiaceae* (divided among *Atriplex*, *Chenopodium*, and *Salsola*) and four species of *Amaranthus*. The data in Table I show that the measurements of the pollen grains of this particular flora overlap to an extent that the distinction of the species is practically impossible.

TABLE I

NO. OF GRAINS	DIAMETER OF GRAIN	DIAMETER OF PORE	DISTANCE BETWEEN PORES
	mμ	mμ	mμ
1	21.58	1.66	4.15
1	23.24	2.49	5.81
1	23.24	3.32	5.81
1	24.90	1.66	2.49
1	24.90	1.66	4.15
1	24.90	2.49	9.96
1	24.90	2.49	3.32
1	24.90	2.49	4.40
2	24.90	2.49	4.15
1	24.90	2.49	6.64
2	24.90	3.32	6.64
1	24.90	3.32	4.98
1	24.90	3.32	8.30
1	26.56	2.49	6.64
1	26.56	3.32	6.64
2	26.56	3.32	4.98
1	26.56	4.15	5.81
1	28.22	3.32	4.98
1	28.22	3.32	8.30
1	29.88	1.66	2.49
1	29.88	3.32	4.98
1	29.88	2.49	4.98

Four per cent of the total grains collected during the year were received in a crushed condition, or were of unrecognized types.

Examination of weather records,⁴ particularly the deviations from normal precipitation and temperature, shows that during the months when this study was made, the weather was slightly drier and warmer than the forty-six-year averages. According to Durham,⁵ the dates of onset, crises, and close of the pollen seasons are practically the same at a given locality each year, except in cases of extreme drought. The weather of 1938 so closely approximated the normal climate that the pollen data presented in Chart 1 are probably typical of average years.

I wish to thank Dr. R. F. Daubenmire for suggesting the problem and directing the research, and Dr. A. E. Brann and Mr. Arthur Nelson for assistance in exposing slides during my absence from Moscow.

INTRAMUSCULAR ADMINISTRATION OF SODIUM SULFAPYRIDINE*

LYNN T. HALL, M.D., EDWARD THOMPSON, M.D., AND
RAYMOND J. WYRENS, M.D., OMAHA, NEB.

INTRAVENOUS and oral administrations of sodium sulfapyridine have been up to now the only routes used in the United States. Most American clinicians have administered the drug intravenously,¹ and many reports have appeared in the literature on this means of administration.^{2, 3, 5, 6} However, the intramuscular route offers certain advantages over the intravenous route if the drug can be given with equal safety. Gaisford⁴ and others have preferred to give the drug intramuscularly.

Before recommending this type of treatment, one should consider certain experimental work. Recent reports of experimental intramuscular injections in guinea pigs showed such therapy to be dangerous and impractical, at least in the guinea pig. Necrotic sloughs occurred frequently, and local reactions were many.⁵ In human muscles, however, the mass of muscle is larger and the total quantity of extracellular space that apparently contains large quantities of chloride is greater, thus providing a factor of safety. Those clinicians opposed to the intramuscular route of administration also contend that this method is likely to produce local irritation and that, even if the drug is deposited into the muscle, a depot may be formed from which prolonged absorption can take place. Furthermore, because of the high pH (11.5) of the material used as compared with normal body fluids, it is argued that this solution is far too alkaline and caustic to be employed with safety. We have not found this to be so.

During the past five months 25 patients have been treated with more than 350 intramuscular injections of the drug.

METHOD OF ADMINISTRATION

A 33 $\frac{1}{3}$ per cent solution of sodium sulfapyridine in sterile water was prepared freshly with each dose of the drug. This preparation was injected deeply into the gluteal or thigh muscles, care being taken that none of the material was deposited into the subcutaneous tissue through the needle tract either upon injection or upon withdrawal of the needle. The schedule of dosage followed closely that used in the oral administration of the drug. Each cubic centimeter of the solution represents 0.33 Gm. At the first injection from 6 to 10 c.c. were given, followed by 3 c.c. every four hours, until the temperature was normal for twenty-four hours. Thereafter the dose was reduced one-half, and its administration was continued for the next five or six days.

*From the Department of Medicine, College of Medicine, University of Nebraska. The material used in this study was furnished by Merck & Co. Received for publication, June 27, 1940.

DISEASES STUDIED

Treatment was not limited to cases of pneumococcal infections but included several other diseases, with varying degrees of clinical success. They are included in this series to demonstrate the efficacy of the route of administration rather than to stress clinical effects of the drug.

ANALYSIS OF DATA

Table I shows a record of treatment of 25 persons with infectious diseases, 14 of whom had pneumonia. Diagnoses were confirmed by culture, typing, and x-ray studies whenever possible. Concentration studies of the drug in the blood were likewise made, and these are recorded. The blood levels recorded in the table represent figures obtained after or during intramuscular injections and before oral administration had been started. These blood levels closely parallel those obtained with the same amount of the drug administered orally. It will be noted that the temperature responses are almost identical with those following the oral administration of the drug. The clinical results appeared to be as good as those obtained by other methods of administration. Toxic effects were strikingly few or extremely mild when noted. In the 25 patients studied there were no local effects of irritation or tumefaction. The patients reported no more pain attendant upon the intramuscular procedure than has been noted after any other parenteral therapy in common use. The only toxic effects noted were four instances of nausea and vomiting; three of these patients had been vomiting before the drug was given. No instances of agranulocytosis, massive red blood cell destruction, or skin reactions were noted in the series.

DISCUSSION

It is not the purpose of this communication to urge the intramuscular administration of sodium sulfapyridine to the exclusion of other routes. However, if it can be shown that this method is a safe procedure, nearly everyone will acknowledge that the technical advantages of this route of administration are many.

Some investigators have noted that muscles are capable of storing metallic drugs as well as other materials with no apparent damage and that absorption takes place thereafter. If such theoretical depots or storage reservoirs are produced, they do not appear to cause demonstrable effects. It is also of interest that adequate levels (3 to 10 mg. per cent) of the drug in the blood may be obtained promptly by this method. Moreover—an important point—once the level is reached, it can be maintained for much more protracted periods than is the case with intravenous therapy. Fenn and his associates⁷ in 1934 and Sandow⁸ in December, 1939, pointed out that 15 per cent of muscle volume is extracellular space, in which all the chloride is believed to reside. If this is the case, it may furnish an explanation for the ease with which a muscle is able to handle the very alkaline sodium sulfapyridine solution.

The technical advantages of giving any drug intramuscularly are many if the procedure is otherwise safe. Gastrointestinal reactions to the drug are avoided. Nausea is usually a very constant symptom when the drug is given

TABLE I
SUMMARY OF DATA CONCERNING INTRAMUSCULAR USE OF SODIUM SULFAPYRIDINE

NO.	PATIENT	DIAGNOSIS	BACTERIOLOGY	NO. OF INJECTIONS	TOTAL AMOUNT OF DRUG (GAL.)	BLOOD LEVEL (MG. %)	TEMPERATURE RESPONSE (F.°)	TOXIC EFFECTS	OUTCOME
1	H. B.	Lobar pneumonia	Positive blood culture Type III	32 in 11 days, none orally	Im.—34	3 to 5	104° to normal in 48 hr.	None	Well
2	A. B.	Lobar pneumonia	Type III	26 in 6 days, none orally	Im.—38	2.3 to 5.4	103° to 100° in 48 hr.	None	Well

20	E. P.	Appendicitis with peritonitis		5 in 2 days, none orally	Im.—6	6.4 after 24 hr.	None	None	Died
21	R. K.	Erysipela; history of pneumonia preceding	No growth	25 in 10 days, then orally	Im.—29 O—4	4.8	None	None	Died
22	E. L.	Paninusitis, glomerulonephritis		9 in 48 hr., none orally	Im.—9		102° to normal in 12 hr.	Moderate nausea and vomiting	Improved
23	B. T.	Aldison's disease, pharyngitis		26 in 8 days, none orally	Im.—27	8.3	103° to 99°-100° in 24 hr.	Little	Improved
24	P. B.	Diabetes, abscess of leg	Nonhemolytic streptococcus	21 in 7 days, none orally	Im.—21	5.9	None	None	Died
25	D. S.	Typhoid fever	Positive Widal	23 in 8 days, none orally	Im.—25		Questionable	None	Well

by mouth, and the condition even progresses to vomiting, which precludes the administration of the drug. In the treatment of comatose patients it is obviously unwise to attempt to make them swallow drugs or to introduce the drugs into the stomach by tube, since in either instance the aspiration of the drug is likely. Old persons with tortuous and sclerotic vessels, infants, children, and women with inconspicuous or no ample sized veins are usually poor subjects for intravenous therapy. Likewise a safe alternative route of administration is always desirable in those cases in which any factor has made the oral or intravenous routes impracticable or impossible.

CLINICAL RECORD OF A TYPICAL CASE

Mrs. A. M., aged 65 years, was admitted to the University Hospital on Dec. 8, 1939, complaining of chills, fever, and cough with bloody sputum. Seventy-two hours before admission she had been suddenly seized with a chill which was soon followed by fever. She began to cough and shortly thereafter felt a sharp pain in the right chest which was aggravated by deep breathing and by coughing.

Her past history is irrelevant except for two attacks of lobar pneumonia, one in 1931, the other in 1934. Each time she made an uncomplicated recovery.

On admission her temperature was 101° F. and rose to 102° F. within two hours. There was limitation of motion of the right chest, with dullness and decreased breath sounds over its lower half. A few moist râles were heard over the same area. Leucocyte count was 15,200, of which 80 per cent were polymorphonuclear in type. Urine was negative. A roentgenogram of the chest, taken by the portable unit, revealed a diffuse density involving the middle third of the right lung field. Sputum examination revealed type III pneumococci.

At eleven o'clock on the night of admission 6 c.c. of $33\frac{1}{3}$ per cent solution of sodium sulfapyridine were administered intramuscularly, followed in four hours by another 6 c.c. The following morning administration of 3 c.c. of solution every six hours was begun and continued for six days. On the morning after admission, after a total of 4 gm. of the drug had been received intramuscularly, examination showed a blood concentration of 3.3 mg. per 100 c.c. Two days later the blood level was 5.4 mg. per 100 c.c. and still later 4.1 mg. per cent.

The patient's temperature on the second day of admission ranged around 100.5° F.; the following morning it dropped to normal where it remained throughout the remainder of her hospital stay. The chest findings rapidly resolved and disappeared entirely by the seventh day after admission. After the second day the patient felt much better subjectively, and at no time was there any indication of local irritation at the site of injection. The patient was dismissed in good health on Dec. 17, 1939, her tenth hospital day.

CONCLUSIONS

1. Twenty-five cases have been analyzed, in which more than 350 intramuscular injections of $33\frac{1}{3}$ per cent solution of sodium sulfapyridine were given.
2. Clinical results of the drug as manifested by blood levels and temperature response were parallel to those obtained by orally administered sulfapyridine.
3. Extreme care must be exercised to insure the deposition of all the drug into the muscle.
4. Toxic effects were minimal. Local evidences of irritation were not seen.
5. There are many technical advantages to this route of administration.

GIANT CELL TUMOR OF THE FRONTAL BONE

J. JAY KEEGAN, M.D., AND CHARLES P. BAKER, M.D., OMAHA, NEB.

THE case of giant cell tumor of the frontal bone in a boy 13 years old is presented here because of the rarity of the lesion in bones which are of the membranous type. Review of the literature discloses only one previous case which was reported by Fraser¹ in 1931. This patient, aged 42 years, following trauma over the left forehead region, developed a mass. The mass was removed surgically and was found to be a soft tissue tumor which contained giant cells on section. Geschickter and Copeland² reviewed a series of 22 cases of giant cell tumor of the skull bones found at Johns Hopkins Hospital and found no instance of tumor which arose in membranous bone. All these cases could be related to centers of ossification arising in cartilage. They reached the conclusion that benign giant cell tumor could not occur in bones which arise membranously. Cotton³ likewise observed that giant cell tumors do not occur in the bones of the skull.

CASE REPORT

A white boy, aged 13 years, was first seen on June 21, 1937, with a protruding mass in the right forehead region. This mass was first noted in 1935, at which time it was thought to be a swelling from an unrecognized trauma. However, progressive enlargement of the tumor mass, which was firm in consistency, painless, and not tender on palpation, discredited this impression. The mass gradually encroached on the right eye, displaced the eye, and restricted its movements. No history of trauma in the region of the tumor mass could be elicited.

The boy was healthy except for the tumor mass above the right eye. In this region there was a smooth, firm, right frontal tumor which measured 5 cm. in diameter and was elevated 1 cm. above the level of the surrounding external table of the frontal bone. The tumor was situated directly above the superior orbital ridge and external angular process of the frontal bone. Laterally it extended across the temporal ridge into the temporal fossa. The right eye was slightly exophthalmic and was displaced medially and downward, with restricted movements laterally and upward.

Received for publication, November 6, 1939.

Roentgenograms (Figs. 1 and 2) of the skull showed an extensive area of decalcification at the site of the tumor between the thinned inner and outer tables of the frontal bone. Medially a very thin, rounded plate of bone was thought to separate the tumor from a small frontal sinus. The frontal sinuses were clear and symmetrical except for slightly less lateral extension on the right. Laterally the tumor extended almost to the limits of the frontal

- Fig. 1.—Frontal roentgenogram of skull showing encroachment of tumor on right frontal sinus and superior orbital plate.

 Fig. 4.—Roentgenogram two years and four months postoperative showing filling of bone defect.

bone at the articulation with the sphenoid and malar bones. The inner surface of the tumor was indefinitely outlined by a rounded, partly absorbed, inner table which seemed to protrude into the cranial cavity about 4 cm. The superior orbital plate was well defined but was depressed about 5 mm. from above and laterally. Some evidence of trabeculation could be seen within the tumor although its general density was little greater than the normal frontal sinus. A preoperative diagnosis of right frontal mucocoele was made.

Fig. 5.—Low-power microphotograph of tumor showing numerous giant cells and fibrous stroma.

Fig. 6.—High-power microphotograph of tumor showing distribution of nuclei in giant cells.

At operation on July 19, 1937 an opening, 2 by 3 cm., was made through a somewhat roughened and almost perforated thin external table over the tumor. Moderately firm, grayish red tumor tissue was found filling the bone defect. An immediate pathologic report was giant cell tumor, possibly xanthoma. The tumor tissue was removed by blunt dissection and curettage with considerable bleeding. The inner table, which was found to be thin and eroded in places, was partly removed from the dura to reduce its impression on the frontal lobe of the brain and to permit some expansion of the frontal lobe into the large cavity where the tumor had been. The superior orbital plate was not removed where it had been depressed by

the tumor. Hemostasis was obtained with difficulty in the region of the lateral tumor bed by means of electrocoagulation. In this region and at other places in the wall some tumor tissue probably remained. The tumor cavity was filled with normal saline, and the scalp was closed without drainage.

Recovery occurred without aspiration or infection. Roentgen radiation therapy was given over the tumor area from July 26 to July 31, 1937, in a dosage of 1035 r. divided into six daily doses. The blood cholesterol determination on July 26, 1937, was found to be 150 mg. per cent, and the blood calcium was 8.8 mg. per cent, both within normal limits. Fluoroscopic examination of all the bones of the body disclosed no evidence of further bone lesions.

The boy has remained well for more than two years since the operation, and the area operated upon shows very little remaining deformity. The right eye does not appear exophthalmic, and its movements are normal (Fig. 3). Roentgenograms taken on Oct. 27, 1939 (Fig. 4) show the area of bone removed by operation surrounded by a smooth wall, considerably reduced in size with no evidence of recurrence of the tumor.

The tissue removed by the surgeon consisted of 32 Gm. of grayish red hemorrhagic tumor. The tissue was very friable and crumbled easily, except that removed from the periphery which was more firm and had more the appearance of fibrous tissue. These firmer areas extended into the central portion of the tumor.

On section the tumor was found to contain great numbers of multinucleated giant cells. In some areas there were from 20 to 40 giant cells in a low-power field (Fig. 5). The giant cells contained from 5 to 25 oval uniformly staining nuclei which had a tendency to be grouped in the center of the cells (Fig. 6). The cytoplasm of the giant cells was homogeneous and stained well with eosin. The giant cells were more abundant at the periphery of the tumor but were present to a lesser extent throughout the tumor. The stroma of the tumor was very cellular and consisted of round and spindle-shaped cells, the former being most numerous. The nuclei of the round cells were similar in appearance to the nuclei of the giant cells. The cytoplasm of the round cells was small in amount. The tumor contained many blood cells both inside and outside of blood vessels.

CONCLUSION

A case of benign giant cell tumor of the frontal bone has been presented. The location of this tumor in membranous bone is unusual since there is only one other case reported in the literature. The theory of Geschickter and Copeland for the origin of giant cell tumor from resorptive processes in cartilaginous bone seems quite reasonable but does not explain the origin of this tumor. We have been unable to find any evidence in the literature of embryology that cartilage is ever present in the frontal bone. We have made no study of the origin of giant cell tumor and have no theory as to the origin of this tumor.

CLINICAL CHEMISTRY

A THEORY OF PORPHYRINOGENESIS*

W. J. TURNER, B.S., M.D., NORTH LITTLE ROCK, ARK.

THERE is no one today who can say how hemoglobin is formed or from what sources its pigmented fraction, protoporphyrin, arises. After a century of study of hemoglobin metabolism there is still nothing known of its anabolic aspects. Between the absorption of food and the appearance of porphyrins and porphyrin compounds in the cells of the body and in excreta there lies an unexplored and undoubtedly important gap.

In the absence of any definite information as to how the various porphyrins arise, a number of hypotheses have been broached, all of which fail to satisfy the requirements of heuristic concepts in two major essentials. In the first place, they leave unexplained one or more of the major factors in the problem; in the second place, they offer no points for direct experimental attacks. Any theory of porphyrinogenesis must explain the following facts:

I. The occurrence of the following porphyrins: protoporphyrin 2, protoporphyrin 9, coproporphyrin I, coproporphyrin III, uroporphyrin I, and uroporphyrin III (Fig. I).

II. The normally great predominance of protoporphyrin 9.

III. The normal appearance of small and equal amounts of the two coproporphyrin isomers.

IV. The extremely rare occurrence of the uroporphyrin isomers.

As a matter of historical interest it is worthy of note that Günther,¹ in his 1911 monograph on porphyria, discussed the possibility that there might be a faulty catabolism of hemoglobin, with the production of "hematoporphyrin" in the liver. This view was shortly proved untenable, at least in its original form, by Fischer's² demonstration that the porphyrins excreted in porphyria are coproporphyrin and uroporphyrin, and that in any event they are of an entirely different isomeric type than is the blood porphyrin. Further studies on porphyria have also revealed that the enlarged liver of true congenital porphyria is not functionally impaired either as an excretory or as a metabolic organ,³ and that acute porphyria not infrequently occurs without evidence of liver damage.^{4, 5} It should not now require proof that the "urobilinogen" of the acute porphyric urine is not urobilinogen at all.^{4, 6}

Following his demonstration that the feces of Petry contained the tetracarboxylic acid coproporphyrin, whereas the urine contained predominantly the octacarboxylic acid uroporphyrin, Fischer^{2c} suggested that the former might arise by carboxylation of the latter in the kidney. This has been aban-

Received for publication, October 26, 1939.

done in view of the improbability that such a reaction could occur biologically. Further, it was soon found that uroporphyrin existed in Petry bone and in his ascitic fluid.⁷

By 1929, when Borst and Königsdorfer⁸ published their monumental treatise on the pathologic examination of Petry, the München school was in agreement that the synthesis of the three main types of porphyrins ran independent courses. In particular, porphyria was regarded as an error of porphyrin anabolism.

Repeatedly suggested, even today, is the possibility that protoporphyrin may give rise to coproporphyrin. This is based on the old idea that the porphyrin excreted in porphyria is hematoporphyrin. It is to be said here that hematoporphyrin is an entirely artificial product of the chemical laboratory and does not occur in nature. The belief was a part of the theory that there might be a faulty breakdown of hemoglobin in the liver. In 1932 van den Bergh, Grotepass, and Revers⁹ claimed that on perfusion of liver with a solution containing protoporphyrin the bile excreted contained coproporphyrin. This experiment has been widely quoted or tacitly used to support later proponents of a catabolic theory of coproporphyrin formation. Aside from the fact that it has never been repeated, and that Fischer has been unable to corroborate it,¹⁰ the evidence presented by the authors is of the slightest sort. Fischer and Orth¹⁰ say: "Möglicherweise handelt es sich hierbei aber um die leichte verständliche Bildung von Hämatoporphyrin IX, an Stelle des Koproporphyrin III." The objection must also be made that the catabolic theory entirely begs the question as to the origin of protoporphyrin.

Later Schreus¹¹ and Carrié¹² proposed a classification of diseases of porphyrin metabolism based on the type of porphyrin excreted. If type I porphyrins were formed, it would be considered a "primary" fault; if type III, it would be "secondary" to a faulty hemoglobin destruction. While some evidence has been presented for this view, and Vannotti,¹³ in particular, leans to it, recent studies on porphyria have shown such a classification to be wholly untenable. Among the objections to it may be mentioned only the necessity of explaining how protoporphyrin may give rise to coproporphyrin; the failure to explain uroporphyrin or protoporphyrin formation; the failure to explain Dobriner's¹⁴ evidence that coproporphyrin formation is associated with erythropoiesis rather than hemolysis; and the inability to explain the simultaneous excretion of both isomeric types of porphyrins, which is the rule rather than the exception.

The faulty hypotheses of the past have been inadequate in large part because of the lack of sufficient data on which to build soundly. Since the discovery of a porphyria with excretion of coproporphyrin III by van den Bergh, Regniers, and Müller¹⁵ in 1928, there has been a realization that sooner or later isomers of the other known porphyrins would be found to occur in nature. This was demonstrated for the uroporphyrins in 1935 by Waldenström,¹⁶ and in the following year by Mertens¹⁷ and by Fischer and Libowitzky.¹⁸ It has since been abundantly confirmed in human,^{18, 19} bovine,²⁰ and squirrel²¹ porphyria that both isomers are excreted simultaneously. Recently, Mertens²² has re-

vealed indeed that in Petry fees the presence of coproporphyrin III in addition to coproporphyrin I had been overlooked, despite its presence in amounts as great as that of the more easily crystallized coproporphyrin I. This is of the greater importance since Grotelpass²³ has reported that the two coproporphyrin isomers occur in equal amounts in normal urine. Recently, Fischer²⁴ has presented evidence that there is also a dualism of the blood pigments, in that, in addition to the previously identified protoporphyrin 9 obtainable from hemoglobin, there is also a small amount of protoporphyrin 2.

Figure 1

In 1936 Rimington,²⁵ appreciating the dualism of the porphyrins, proposed a schematic theory of enzyme action controlling not only the rate and type of porphyrins production, but also the formation of different porphyrins. His postulates, however, were too generalized for closer definition and merit no attention. In the same year, at the Baltimore meeting of the Southern Medical Society, Dobriner put forth a theory, published in 1937,^{14a} that definitely proposed a chemical mechanism of porphyrinogenesis in keeping with known facts.

According to Dobriner, it is postulated that there are formed two pyrromethenes, A and B, which may combine in any of three possible ways: A + A

will give a type I porphyrin; B + B, a type II porphyrin; A + B, a type III porphyrin.

Type II porphyrins have not so far been discovered in biologic material, and Dobriner was led to suppose an enzymatic action which would act in such manner as to agree with actual facts. It will be noted that this ingenious theory still fails to explain the occurrence of three kinds of porphyrins.

By a glance at the formulas in Fig. I it will be apparent that these three kinds of porphyrins may be considered to be comprised of no more than three structural units; namely, 2-acetic acid, 3-propionic acid pyrrol; 2-methyl, 3-propionic acid pyrrol, and 2-methyl, 3-vinyl pyrrol, of the structures in Fig. III.

Figure II

Figure III

Figure IV

By simple decarboxylation of the acetic acid group pyrrol I is transformed into pyrrol II; dehydrogenation and decarboxylation of pyrrol II leads to pyrrol III. These reactions are well known in biologic processes, and it is not unimaginable that pyrrol I may actually be the primary building block of the naturally occurring porphyrins.

Such a pyrrol may well undergo an aldehyde synthesis to form a pyrromethene. Corwin and Andrews²⁶ have shown that in the aldehyde synthesis of pyrromethenes there is an intermediary formation of a tripyrrylmethane. It is of considerable interest that at least once in the experiments of Nature such a compound has been formed as a blind alley. This compound, prodigiosin, has been given the structure in Fig. IV.²⁷

It may now be seen that if such a tripyrrylmethane were to be formed of the pyrrol I units, it may have the following form, which, on passing to the pyrromethenes, may lead to uroporphyrins I, II, and III:

Such a synthesis must be very rare, for it is seldom found, and it must occur only when the acetic acid group is protected from decarboxylation. Fischer

and Hofmann,²⁸ and Fischer and Müller²⁹ have shown that pyrroles of the type under discussion are unstable, losing carbon dioxide spontaneously at room temperatures.

The formation of an homologous trimethyl, tripropionic acid tripyrryl-methane might explain the formation of the coproporphyrins.

Figure V

However, the predominance of protoporphyrin as the apex of pyrrol metabolism indicates strongly that the extent of formation of pyrrol III must be large. The formation of protoporphyrin 2 and protoporphyrin 9 may then be accounted for by the intermediate formation and decomposition of a tripyrryl-methane according to the course indicated in Fig. VI.

In this theory, as well as in Dobriner's, there is expected the formation of some type II porphyrin (protoporphyrin 5). If the theory is correct, this will be found, unless there is some purely chemical reason, possibly associated with substituents on the 1 or 4 positions of the pyrrole rings, which would preclude it. It is, of course, likely that porphyrins are not formed without the action of enzymes, but of them nothing is known at present. However, the fact that uro- and coproporphyrins almost universally occur as their zinc complexes^{6, 21, 30, 31} suggests that this metal may play a part in their formation.

Concerning the source of the proposed pyrrol I there is little to be said. Certainly it cannot arise from chlorophyll or any of its derivatives. Here it may be pointed out that there is no reason to believe that chlorophyll plays any part in the formation of animal porphyrins. Among the amino acids only tryptophan could conceivably be a precursor of pyrrol I, and this would require the improbable but possible opening of the 6-membered ring. This might occur by an oxidative scheme, such as is known with tyrosine and with quinone (Fig. VII).

However, as has been pointed out by Thomas,³² there is no good evidence that tryptophan is essential in the formation of hemoglobin. Indeed, the work

of Fischer and his students, investigating the production of coproporphyrin by yeast,³³ and the study of Thomas³² with the Harder's glands of rats as an indicator of protoporphyrin production, point to the probability that carbohydrate and simple amine metabolism is closely related to porphyrinogenesis.

Figure VI

Figure VII

Finally, we may briefly consider the site of porphyrin formation. The rediscovery of cytochrome by Keilin in 1925, and the simultaneous demonstration of coproporphyrin synthesis by yeasts, reported by Fischer and his associates,³³ has been corroborated many times^{30, 35} over. It is now plain that every unicellular organism is capable of forming its own porphyrins, and there is considerable evidence that this is indeed a general as well as an ancient cellular function. This formation appears to be characteristic of growing cells, so that in an adult animal the formation of porphyrins due to the majority of cells is probably slight. In view of the great activity of the erythropoietic system in the formation of hemoglobin, it is here that the evidences for cellular porphyrinogenesis must be sought. Indeed, it is here that the most straightforward evidence is found. Repeatedly, fluorescence characteristic of the three types of porphyrins has been observed in erythroblasts, gradually fading as the addition of iron and protein dampened it.^{8, 13, 36} However, in porphyria, the frequent demonstration of zinc uroporphyrin,³¹ as well as of other porphyrins^{8, 13, 37} in the peripheral portion of liver lobules, suggests the possibility that in this condition cells other than erythropoietic may be active in porphyrinogenesis.

SUMMARY

A theory of porphyrinogenesis is proposed, based upon the postulated original formation of a 2-acetic acid, 3-propionic acid pyrrole, the products of which,

by passing through an aldehyde synthesis over a tripyrrylmethane, may form protoporphyrins 2 and 9, coproporphyrins I and III, and uroporphyrins I and III. The nature of the fundamental disturbance of metabolism in porphyria is suggested. The sources and sites of porphyrin formation are discussed.

STUDIES ON THE INTRAVENOUS INJECTION OF COLLOIDS*

II. EFFECTS OF GUM ACACIA ON CERTAIN FUNCTIONS OF THE LIVER WITH A NOTE ON ITS EFFECTS ON THE PRODUCTION OF IMMUNE BODIES

W. KNOWLTON HALL,† PH.D., NEW ORLEANS, LA., AND R. B. GIBSON, PH.D.
AND L. A. WEED, M.D., PH.D., IOWA CITY, IOWA

ANDERSCH and Gibson¹ in 1934 demonstrated in a series of experimental observations that a large part of the gum acacia injected intravenously in rabbits and in dogs was not excreted, as had been generally assumed, but was deposited in the hepatic cells. An average of 30 and 33 per

*From the Pathological Chemistry Laboratory, University Hospitals, the State University of Iowa, and the Department of Biochemistry, School of Medicine, Louisiana State University, New Orleans.

†This report includes a condensation of a portion of a dissertation submitted in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Department of Chemistry, in the Graduate College of the State University of Iowa, July, 1936. A preliminary report appeared in *Proc. Soc. Exper. Biol. & Med.* 38: 46, 1938.

Received for publication, November 20, 1939.

cent, respectively, was found in the livers of two dogs studied, and an average of 50 per cent in the livers of rabbits. Histologic examination of the liver tissue, and marked changes in the composition of the bile, especially of the bile pigment excreted by the dogs under observation, led these authors to conclude that intravenous injections of gum acacia were likely to cause marked liver damage. In the same contribution they reported a fatal clinical case of nephrosis in which this form of therapy had been employed and in which 43 per cent of the injected acacia was found in the liver. The liver cells presented the same characteristic vacuolated appearance noted in the liver cells of the experimental animals.

In the following year Dick, Warweg, and Andersch² extended these clinical and experimental observations and concluded that the intravenous use of gum acacia in patients with nephrosis was likely to be attended with harmful effects.

In 1937 Studdiford¹ called attention to the extreme danger of employing intravenous injections of gum acacia in patients with already damaged livers, such as are likely to be found in the toxemias of pregnancy and similar disorders. This form of therapy, he pointed out, might interfere with the gaseous exchanges of the red blood cells, and if carried to a marked degree, might produce severe or fatal anoxemia, especially if faulty solutions were employed. He also produced evidence to show that such solutions might cause "conglutination of the red cells, with resultant capillary blockage followed by edema and hemorrhage."

The purpose of the present contribution is twofold: to study liver function by various tests after the experimental intravenous injection of acacia, and to observe the possible effects of this method of treatment on the production of immune bodies. The general procedures employed in the handling of the experimental animals and the injection of the gum acacia, together with the methods of analysis used for acacia, are set forth in detail by Andersch and Gibson.¹

STUDIES IN LIVER FUNCTION

Glucose and Galactose Tolerance Tests.—Glucose and galactose tolerance tests were performed on normal dogs after they had fasted eighteen hours or more. Blood for a control sugar determination⁴ was taken from the marginal vein of the ear, and other samples were taken every half hour for a two-hour period following the administration by stomach tube of 1.5 Gm. of sugar per kilogram of body weight (Table I). The blood galactose,⁵ as well as the total sugar, was determined subsequently in two more dogs in the course of the galactose tolerance tests. All the dogs were then given from three to seven intravenous injections of gum acacia (totaling 4.4 to 10.7 Gm. per kilogram of body weight) over periods varying from three days to four weeks. Several days after the last acacia injection the glucose and galactose tolerance tests were repeated.

The control glucose curves obtained in this study are similar to those obtained by Bodansky⁶ after the oral administration of sugar, and by Soskin, Allweiss, and Cohn⁷ after its intravenous administration. The curves ob-

tained after the injections of acacia apparently correspond with the glucose tolerance curves obtained by Soskin and Mirsky⁸ in severe liver intoxications.

The galactose blood clearance controls agree with the curves obtained on normal dogs by Bodansky.⁶ A marked diminution in galactose tolerance was observed after the injection of acacia.

*The total sugar values obtained in these tests are reported on the same line on the right side of the table.

Tetraiodophenolphthalein and Bilirubin Tests.—Dogs were tested by a modification of the sodium tetraiodophenolphthalein liver function procedure of Graham.⁹ Ninety seconds after the injection into the jugular vein of 25 mg. per kilogram body weight of tetraiodophenolphthalein (isoiodeikon), a sample of blood was withdrawn from the vein on the opposite side and oxalated. Additional samples of blood were obtained fifteen, thirty, and sixty minutes later. One cubic centimeter of plasma from each specimen was made alkaline with 2 drops of 10 per cent sodium hydroxide, 10 c.c. of ethyl alcohol were added, the contents of each tube were mixed, placed in the ice-box overnight, and centrifuged in the morning. The test of the first blood sample was used as a standard for the colorimetric determination of the dye in the subsequent specimens.

Observations on four dogs revealed no significant changes in the ability of the liver to excrete the dye before and after injections of gum acacia; in two other dogs there was apparently a slight reduction.

For the bilirubin test the method suggested by Soffer¹⁰ was employed. One milligram of bilirubin per kilogram of body weight was given intravenously to two normal dogs and to two dogs which had had intravenous

injections of acacia (Table II). Samples of blood were withdrawn before injection of the pigment, and again five minutes and four hours afterward. The plasma bilirubin in the specimens was determined quantitatively by the Gibson and Goodrich¹¹ modification of the van den Bergh procedure. The Soffer method, which was suggested for clinical use, gave a rather low degree of bilirubinemia. We therefore repeated the test, using the procedure suggested by Dragstedt and Mills.¹² Ten milligrams of bilirubin per kilogram of body weight were injected intravenously, and blood samples were withdrawn before the injection, and five minutes, thirty minutes, one hour, and two hours afterward. In none of the four dogs used was there any alteration in the rate of removal of the injected bilirubin.

*The total sugar values obtained in these tests are reported on the same line on the right side of the table.

Tetraiodophenolphthalein and Bilirubin Tests.—Dogs were tested by a modification of the sodium tetraiodophenolphthalein liver function procedure of Graham.⁹ Ninety seconds after the injection into the jugular vein of 25 mg. per kilogram body weight of tetraiodophenolphthalein (isoiodeikon), a sample of blood was withdrawn from the vein on the opposite side and examined. Additional samples of blood were obtained fifteen, thirty, and sixty minutes later. One cubic centimeter of plasma from each specimen was made alkaline with 2 drops of 10 per cent sodium hydroxide, 10 c.c. of ethyl alcohol were added, the contents of each tube were mixed, placed in the ice-box overnight, and centrifuged in the morning. The test of the first blood sample was used as a standard for the colorimetric determination of the dye in the subsequent specimens.

Observations on four dogs revealed no significant changes in the ability of the liver to excrete the dye before and after injections of gum acacia; in two other dogs there was apparently a slight reduction.

For the bilirubin test the method suggested by Soffer¹⁰ was employed. One milligram of bilirubin per kilogram of body weight was given intravenously to two normal dogs and to two dogs which had had intravenous

almost specifically utilized by the liver. The galactose curves are more decisive, and the diminution of galactose tolerance noted after the injection of acacia undoubtedly indicates liver damage. The impairment of glycogenic function after acacia injection is also borne out by post-mortem observations on liver glycogen made on three dogs. The livers contained respectively 6.6, 7.7, and 6.9 per cent of glycogen, an average of 7.1 per cent against the normal value of 15 per cent to be expected in dogs fed, as these were, a high carbohydrate diet. Bollman and Mann¹⁸ have observed that dogs with 80 per cent of the liver removed are still able to take care normally of glucose and galactose.

The figures which Soffer¹⁰ gives in an extensive review (including his own work) show that an abnormal retention of bilirubin is more closely correlated with the degree of liver damage than are the bromsulphalein or the levulose tolerance tests of liver function. We found no significant alteration in the rate of removal of injected bilirubin before and after the injection of gum acacia, and only a slight variation in two dogs in the excretion of tetraiodophenolphthalein. It seems logical to conclude, therefore, that this special function of the liver is not affected by the injection of acacia.

The experimental studies of Whipple and his co-workers¹⁹⁻²¹ point to the liver as the source of serum albumin and globulin. A number of studies by others²²⁻²⁶ are concerned with the effect of severe liver disease on the plasma proteins, particularly papers by Snell²⁵ and by Myers and Keefer.²⁶ These bear out Snell's conclusion that in advanced chronic hepatic lesions there is "a moderate reduction in the total serum proteins, the diminution occurring chiefly in the albumin fraction." Dick, Warweg, and Andersch² have shown that repeated injections of acacia in children with nephrosis resulted in a reduction of blood serum protein, chiefly albumin. They also found that daily injections of acacia into dogs caused a sharp drop in the serum albumin and a less marked fall in the globulin, both values returning to normal when the injections were discontinued. Our own observations are in accord with these results, as are the more recent studies of Heckel and his associates.²⁷

Foster and Whipple²⁸ have shown that fibrinogen is formed exclusively by the liver. Low values may be found in hepatic disease, though the picture may be complicated by the stimulating effects of infection on fibrinogen production. The effect on fibrinogen levels of various clinical and experimental conditions involving the liver has been reviewed by Starlinger and Winands²⁹ and by Ham and Curtis.³⁰ It may be said that complete extirpation of the liver in dogs³¹ and in rabbits³² results in a rapid fall in plasma fibrinogen, in some experiments amounting to 50 per cent in twenty-four hours; removal of as much as 70 per cent of hepatic tissue, on the other hand, has no effect on the fibrinogen level.

Foster and Whipple,³³ who found lowered blood fibrin values after the injection of acacia, ascribed the reduction to dilution of the blood. The possible influence of gum-saline solutions on blood coagulation is mentioned by Takata³⁴ and others. Dieckmann,³⁵ who tried gum acacia injections in the treatment of eclampsia, specifically warns that this form of therapy may cause a pronounced drop in blood fibrin. The decrease in hemoglobin, the increased bleeding time, and the low fibrinogen values noted in our experimental animals after the injection

*The titration of antibodies "before immunization" with Dogs 5, 6, and 7 was done on blood drawn three days after the first injection of antigen. Dogs 3 and 7 are normal animals.

tion of gum acacia are undoubtedly significant and would seem to indicate a rather severe degree of liver damage. Additional confirmation is found in the death of one dog from a postoperative hemorrhage after several injections of gum acacia.

EFFECT OF COLLOIDS ON THE PRODUCTION OF IMMUNE BODIES

The injection of various colloids has been shown to result in a marked reduction in the ability of the animal to produce immune bodies.³⁶ These studies have led to an association of the reticulo-endothelial system with antibody production. However, the hepatic cells of the liver have never been definitely excluded from a role in antibody formation. The plasma proteins which carry the antibodies of the blood have their origin in the liver, and the ability of the organism to produce these proteins is impaired by the acacia which is deposited in the hepatic cells. Acacia itself is at most only a very mild antigen.^{37, 38}

In order to determine the effect of acacia injections upon the ability of the dog to produce immune bodies, five animals, of approximately equal weight, were used. Three of them (Nos. 2, 5, and 6) had had intravenous gum injections and had been tested by various liver function tests (Tables I, III, and IV). The other two (Nos. 3 and 7) were used as controls.

Two antigens were used. The first was a 5 per cent suspension of pooled washed human erythrocytes. The second was a vaccine of *Vibrio cholera* made from whole and ground organisms which had been killed by phenyl mercuric nitrate, 0.12 per cent; the cholera was strain No. 23 of the American Type Culture Collection. Five cubic centimeters of the suspension of human red blood cells were injected intravenously every three days until five injections had been given; 0.1 c.c. of the cholera vaccine was injected intravenously with the erythrocyte suspension for three days, and 0.2 c.c. for the last two days. Eight days after the final injection of the antigens the animals were bled and the titer of agglutinins, precipitins, and bacteriolysins or hemolysins was determined. Samples of blood drawn before immunization were also checked for the presence of antibodies.

The presence of cytotoxins for *Vibrio cholera* could not be demonstrated in either the normal or the immune sera. Hemolysin titrations were not very satisfactory, and the titers produced were low. Differences between the titers of antibody produced by normal dogs and those receiving acacia were not significant, and the data all indicate that gum acacia has no effect upon the production of immune bodies (Table V). This lack of effect is in marked contrast to the reduction of antibody formation likely to result when colloids which definitely block the reticulo-endothelial system are injected.

SUMMARY AND CONCLUSIONS

1. Repeated intravenous injections of gum acacia solution in dogs resulted in evident damage for carbohydrate and serum protein metabolism functions of the liver, as evidenced by changes in the glucose and galactose blood sugar tolerance curves and determination of the plasma proteins.

2. The blood clearance of injected tetraiodophenolphthalein and bilirubin was not significantly affected.

BLOOD SERUM MAGNESIUM IN BRONCHIAL ASTHMA AND ITS TREATMENT BY THE ADMINISTRATION OF MAGNESIUM SULFATE*

VICTOR G. HAURY, M.D., PHILADELPHIA, PA.

A NUMBER of investigators have recently shown that magnesium salts will protect animals against anaphylactic shock. Delbet and Palios¹ have found that a sensitized guinea pig may be protected against the provocative injection of the specific antigen by parenteral injections of magnesium salts. Lumière and Monchal² have also found that sensitized rabbits may be protected by one or more daily injections of 0.1 Gm. per kg. of magnesium thiosulfate. They observed that such injections of the thiosulfate produced a 50 to 100 per cent increase in blood cholesterol and concluded that the antishock action of this salt was due entirely to the cholesterolemia it produced. I³ have observed, however, that if the serum magnesium of sensitized guinea pigs is increased to about 8 mg. per 100 c.c. immediately before the provocative injection of the antigen is made, anaphylactic shock may be prevented. This would seem to indicate that hypermagnesemia rather than a cholesterolemia is the protective agent. If hypermagnesemia will prevent anaphylactic shock, we may hypothesize that hypomagnesemia may make one more sensitive to, or even incite an anaphylactic reaction.

The similarity between the bronchial spasms in anaphylactic shock and bronchial asthma is now generally conceded. The possibility that a hypomagnesemia may be an etiologic factor in bronchial asthma naturally suggested itself. The findings of Rosella and Plá⁴ that intravenous injection of magnesium sulfate relieved a case of asthma which was unaffected by the common remedial agents, adds an additional premise to this theory. ✓

The present investigation was undertaken to determine, if possible, if patients suffering from bronchial asthma have a concomitant hypomagnesemia.

METHOD

Sixty-six asthmatic patients were chosen at random as admitted to the Allergy Clinic and the Medical Wards of the Jefferson College Hospital.†

About 10 c.c. of blood were collected from each patient from the median basilic vein. Serum magnesium determinations were made by the Titan yellow method described elsewhere.⁵ In the hospitalized patients a series of determi-

†I wish to thank Doctors J. A. Clark and H. A. Reimann, Chiefs of the Allergy and Medical Services, respectively, of the Jefferson College Hospital, for their cooperation in making this investigation possible.

nations were made at daily intervals. The serum magnesium values of 40 normal medical students were previously ascertained. As the ingestion of food has very little influence on the concentration of serum magnesium, no effort was made to obtain blood at any specified period in relation to meals. All determinations were made in duplicate.

RESULTS

Normal Persons.—Forty determinations were made, using blood obtained from students in the medical school. The values obtained varied between 1.74 and 3.10 mg. per 100 c.c. serum, with a mean value of 2.33 mg. These figures are in accordance with those found by Beecher,⁶ Bomskov,⁷ Waeker and Fahrig,⁸ Walker and Walker,⁹ and Hirschfelder and myself.¹⁰

Serum magnesium values below 1.7 mg. per 100 c.c. serum are, therefore, considered as being definitely below normal. Values above 3.1 mg are considered as being high.

Asthmatic Subjects.—The serum magnesium of the 66 individuals suffering from bronchial asthma varied between 1.1 and 3.15 mg. per 100 c.c., with a mean value of 2.13 mg. Of the entire group of 66 individuals 16 (24.2 per cent) had a low serum magnesium, varying from 1.1 to 1.7 mg. per 100 c.c., with a mean value of 1.52 mg. Twenty-six of the patients examined were suffering an acute attack of asthma at the time the blood samples were taken. In these the serum magnesium values varied between 1.1 and 3.1 mg per 100 c.c., with a mean value of 1.82. The remaining 40 individuals were free of asthma at the time the blood was analyzed. In these the mean magnesium value was 2.32 mg. per 100 c.c. serum (see Table I).

Upon further analysis of the data, one finds that of the 26 patients having acute asthmatic spasms, 13 (50 per cent) had a concomitant hypomagnesemia. In this latter group the serum magnesium varied between 1.10 and 1.70 mg., with a mean of 1.50 mg. per 100 c.c. The serum magnesium of the 13 remaining cases was entirely within normal range.

The Effect of Injections of Magnesium Sulfate.—Two patients suffering from severe asthma were treated with intravenous and intramuscular injections of magnesium sulfate. The results obtained were essentially the same as those reported by Rosella and Plá.⁴

Two white male patients, aged 39 and 56 years, respectively, hospitalized at the Jefferson Medical College Hospital, were suffering with acute bronchial asthma. Both patients had a low serum magnesium, averaging 1.53 and 1.60 mg. per 100 c.c., respectively, over a four-day period. Epinephrine administration was required every four to six hours, but on several occasions this drug was ineffective. This form of treatment was discontinued, and at the height of the asthmatic paroxysms 20 c.c. of 10 per cent magnesium sulfate were injected slowly intravenously and 4 c.c. of the 50 per cent solution were given deep intramuscularly. Both patients were relieved immediately and remained free of asthma for eighteen and twenty-eight hours, respectively. Following the reappearance of the bronchial spasms, epinephrine therapy was again instituted, requiring as before, an injection every four to six hours.

DISCUSSION

The majority of patients examined did not have any attacks of asthma for a period of from one day to more than three months previous to the time the blood was examined. It is to be expected, therefore, that normal values should be found in these cases. It seems significant, however, that one-half of the cases examined during acute attacks of asthma should be found to have a definite hypomagnesemia. It appears even more significant that of the 16 individuals having a low serum magnesium, 13 should be suffering from an acute attack of asthma. The degree of hypomagnesemia, however, was not in proportion to the severity of the attacks. Patients S. R. and C. P. with relatively mild asthma were found to have magnesium values of 1.20 and 1.35 mg. per 100 c.c. serum, respectively. Patients E. S. and J. Q., on the other hand, suffered severe and persistent attacks, although the magnesium content of their blood was 1.53 and 1.60, respectively. Three individuals with a hypomagnesemia did not have any attacks for 2, 6, and 21 days, respectively.

That 50 per cent of the patients having acute attacks of asthma should have a low serum magnesium indicates that a hypomagnesemia and bronchial asthma may have some relationship. It appears quite plausible, at least in some cases, that a deficiency of this ion may upset the neuromuscular mechanism to such an extent as to make certain individuals more susceptible to bronchial spasms. It has been conclusively shown by Kruse and his collaborators^{11, 12} and others¹³⁻¹⁶ that such an ionic deficiency manifests itself chiefly by muscular spasms and convulsions. We must remain cognizant, however, of the possibility that the hypomagnesemia may be the result of the bronchial asthma.

Of equal importance is the fact that 50 per cent of the patients examined during attacks of asthma had normal serum magnesium. This means that a hypomagnesemia is by no means an essential etiologic factor. At present we may conclude that a disturbance in magnesium metabolism may be a contributing factor in a certain percentage of patients suffering from bronchial asthma. Further investigations in this direction should prove most interesting.

SUMMARY

1. The serum magnesium of 40 normal medical students varied between 1.74 and 3.10 mg. per 100 c.c., with a mean value of 2.33 mg.
2. The blood sera of 66 patients suffering with bronchial asthma were analyzed for their magnesium content with an analysis of the results.
3. The treatment of two patients with parenteral injections of magnesium sulfate is reported.

SODIUM AND POTASSIUM STUDIES IN PERSONS WITH AND WITHOUT ARTERIAL HYPERTENSION*

DUDLEY W. BENNETT, M.D., SAN FRANCISCO, CALIF.

THE relation of sodium and potassium to arterial blood pressure has not been studied extensively. It is, of course, well known that in adrenal cortical insufficiency (Addison's disease) hypotension and a low serum sodium and a high serum potassium occur; and conversely, in the hyperadrenal-cortical state the opposite is observed, namely, hypertension and a high serum sodium and low serum potassium.^{1, 2} There is, however, no evidence to show that the altered sodium and potassium levels are directly related to the altered state of the blood pressure. Furthermore, McCance³ has pointed out that the findings of a low serum sodium associated with a high blood pressure are quite common in interstitial nephritis.

The following study has been carried out to determine, if possible, whether the subject with arterial hypertensive disease might reveal some evidence of a disturbance in sodium and potassium metabolism when these two elements were drastically restricted in the diet.

A group of five male subjects was placed on a diet low in sodium and potassium content. Three of the subjects studied (J. L. B., aged 70 years; J. F. W., aged 58 years; and W. L. S., aged 28 years) had had definite elevation of systolic and diastolic blood pressures of from one to twelve years' duration, with

*From the Department of Medicine, University of California Medical School, San Francisco.
Received for publication, November 2, 1939.

or without evidence of renal disease but without evidence of abnormal retention of fluid. None of the subjects gave evidence of nitrogen retention in the blood.

The two persons in the control group (W. Y. B., aged 21 years and J. A. N., aged 24 years) had normal blood pressure readings and no evidence of fluid retention. W. Y. B. had an anxiety neurosis, and had had before the study was undertaken a systolic blood pressure reading as high as 150. His diastolic blood pressure was at all times within normal limits. Immediately before and during the study his systolic blood pressure was within normal limits.

All patients were confined to the hospital for observation for periods of from two to fifteen days before the study was begun. During the study their physical activities were restricted to such exercise as walking about the ward. At no time was abnormal sweating present. The environmental temperature was fairly constant, maintained at approximately 22° C. During a preliminary period of twenty-four hours, the fluid intake, urinary output, blood pressure, and body weight were determined. At the end of this period venous blood was obtained after the patient had been fasting for fourteen hours, for determination of the serum sodium, potassium, and protein; the plasma nonprotein nitrogen; and the blood sugar, chlorides, and carbon dioxide (see Table II and Chart 1).

The subjects were then given a special diet, which had been prepared under the supervision of Miss A. Huesman, of the Dietetic Department of the University of California Hospital.

SPECIAL MIXTURE*

Daily portion:

125 Gm. of dry uncooked white rice

125 Gm. of washed cottage cheese

10 Gm. of pure glucose

Method of preparation:

Wash rice thoroughly; drain. Mix rice with 1½ quarts of distilled water. Place in heavy kettle over direct heat. Boil for twenty minutes; drain in sieve. Mix rice that has been drained with 1 quart of distilled water and boil for ten minutes. Drain. Repeat last process and drain.

Purée commercially prepared cottage cheese through very fine strainer. Place in cheesecloth bag. Wash in 2 quarts tap water, kneading thoroughly; drain. Repeat process eight times. Repeat ninth time using distilled water. Drain overnight. Weigh 125 Gm. of washed cottage cheese.

Mix together cooked rice, washed cottage cheese, and glucose that has been dissolved in ½ cup distilled water. To this mixture add distilled water until the total weight of mixture equals 810 Gm.

Food value:

Protein 25 Gm.

Fat 2 Gm.

Carbohydrate 113 Gm.

Total number of calories 610

A sample of each batch of food so prepared was analyzed for the sodium and potassium content (see Chart 1).

The fluid intake, exclusive of the diet described above, was limited to 1,000 c.c. of distilled water in twenty-four hours. It was found that this amount of

*A sufficient amount of food for each subject was made at one time for the duration of the test.

fluid satisfied the thirst requirement while taking the diet. Occasionally a patient would take even less than the amount permitted (see Table I).

All the determinations of sodium and potassium were made, using the method described by Butler and Tuthill⁴ for the sodium, and that described by Shohl and Bennett⁵ for the potassium with the modifications suggested by Strauss.⁶ The urine sodium determinations were made as described by Butler and Tuthill⁴ without modifications in technique. The other specimens for sodium and potassium determinations were first dried on a hot plate and then ashed in a muffle furnace at 600° C. for approximately eight hours. In collecting all the specimens, care was exerted to maintain a uniform procedure. No evidence of hemolysis was observed in any serum specimens.

*Blood pressure readings of W. L. S. were found to be as high as 200/135 several weeks before the study. He was confined to the hospital for fifteen days for observation before the study was begun.

All other chemical determinations on the blood serum and plasma were made by Mrs. T. Leake of the Central Laboratory of the University of California Hospital.

In each instance, the low sodium and potassium intake was continued for three days. During this time daily specimens of blood were obtained for determination of the sodium and potassium content of the serum when the individual had been fasting for fourteen hours. All urine excreted was collected in twenty-four-hour lots and was measured for amount, specific gravity, and pH (Table I). The twenty-four-hour output of sodium and potassium excreted in the urine was determined (Chart 2). The blood pressure and the body weight were likewise determined daily when the subject had been fasting (Table I). At

the end of the three-day period all the chemical determinations of the blood serum and plasma were repeated (Table II).

Three persons (J. F. W., W. L. S., and J. A. N.) were continued on the same diet and fluid intake but with the additional administration of 6 Gm. of potassium chloride in enteric coated tablets for two days longer.

Two other patients were studied in the same manner. The first was in the normal group and the second had a history of arterial hypertension of at least ten years' duration but had normal blood pressure readings during the study. The results obtained in these persons are not reported in this paper because of incomplete data. Such data as were obtained, however, in both persons were similar to those obtained in other normal persons.

Chart 1—Blood serum level of sodium and potassium, normal and low sodium and potassium intake.

J.L.B. Essential hypertension (late)	→ Trace	0.1831
J.A.N. Control	→ 0.1220	0.04618

It was fully appreciated that the methods utilized in this study to restrict the intake of sodium and potassium were inadequate as far as normal diet requirements are concerned, and that the duration of the experiment was of a comparatively short period of time. However, it was felt that the reaction of the individual to salt deprivation might be tested in a more satisfactory manner by drastic restriction of both sodium and potassium for a shorter time than by permitting the person to have a less restricted intake of these two elements over a longer period of time. To prolong the drastic limitation of sodium and potassium intake would lead to a state of marked salt deficiency. It was felt that such a salt-deficient state would introduce faults in metabolism sufficient to render the interpretation of data obtained more difficult.

As mentioned above, no noticeable perspiration was present in any person during the experiment. No attempt, therefore, was made to measure or to

analyze the fluid lost in the perspiration or to provoke excessive loss of fluid by artificial means, as has been reported by McCance.⁷

Tables I and II give data other than the sodium and potassium determinations. Charts 1 and 2 show in graphic form the fasting daily sodium and potassium blood serum levels and the daily excretion of sodium and potassium in the urine; they also give notation of the sodium and potassium intake in twenty-four hours.

Chart 2.—Excretion of sodium and potassium in the urine, normal and low sodium and potassium intake.

DISCUSSION

Although the serum sodium level fluctuated in each individual when the sodium and potassium were restricted drastically, this change was of a minor degree in all five curves. When the two curves for the normal controls are compared with those for the patients with hypertension, no definite difference is seen between the levels of blood serum sodium in normal persons and the levels in persons with arterial hypertension.

The levels of serum potassium, however, fell following deprivation of sodium and potassium. It should be noted that in patients with definite arterial hypertension (J. L. B., J. F. W., and W. L. S.) a greater drop occurred than in two normal persons (W. Y. B. and J. A. N.). One normal individual (J. A. N.) at first had a moderate drop in the potassium level followed by a rise to above his normal level when sodium and potassium were restricted.

Chart 2 shows that the urinary output of both sodium and potassium decreased when these elements were restricted in the diet.

Two of the three patients (J. F. W. and W. L. S., both having arterial hypertension) on whom the experiment was continued for an additional two days with the addition of 6 Gm. of potassium chloride daily, failed to regain during this period their normal fasting levels of blood serum potassium. The change in the blood serum sodium in this group was of a minor degree. The addition of potassium chloride caused a definite increase in the excretion of potassium in the urine, with very little change in the amount of sodium excreted.

It was considered that the fall in blood pressure was probably due to several factors, namely, restriction of food and fluid intake as well as rest. Other data, such as fluid balance, body weight, and urinary pH shown in Table I, and serum protein, plasma chloride, sugar, and carbon dioxide combining power in Table II, showed only moderate variations and were considered to be of no great significance. It will be recalled that McCance⁷ demonstrated very marked changes in such blood constituents as serum proteins, urea, chlorides, and sodium in his patients in whom he produced a sodium chloride deficiency. None of the persons reported in this paper complained of the symptoms reported by McCance, such as aberrations of flavor, cramps, weakness, and lassitude. It is quite safe to conclude from our data in Tables I and II that our patients were not in a salt-deficiency state.

A rise was noted in the nonprotein nitrogen level of the blood plasma in all persons following sodium and potassium restriction.

It is well known that potassium is held largely in the intracellular fluid and sodium is held in the extracellular fluid. It was found in this study that the potassium level of the blood serum falls when the intake of both sodium and potassium is restricted. The significance of the greater decrease in the serum level of potassium in the patients with arterial hypertensive disease is not clearly understood at the present time.

SUMMARY AND CONCLUSIONS

In five male patients studied drastic restriction of sodium and potassium in the diet for a period of from three to five days produced no significant change in the blood serum level of sodium, but caused a drop in the blood serum level of potassium. This drop in the potassium level was of a greater magnitude in the three persons who had definite arterial hypertensive disease than in those who had normal blood pressure.

The urinary excretion of both sodium and potassium decreased with restriction of these two elements in the diet.

NOTE: Since the completion of the study here presented, my attention has been called to a paper by O. L. U. S. DeWesselow and W. A. R. Thomson entitled, "A Study of Some Serum Electrolytes in Hypertension," in the *Quart. J. Med.* 8: 361, 1939. These authors pointed out that in their experiments the serum of patients suffering from essential and malignant hypertension tended to show a lower level of potassium than that of patients with a normal blood pressure on the same diet.

THE EFFECT OF IRON ON PHOSPHORUS, CALCIUM, AND NITROGEN METABOLISM*

ADELAIDE P. BARER, PH.D., AND WILLIS M. FOWLER, M.D.
IOWA CITY, IOWA

THE administration of certain metals to experimental animals produces a low blood phosphorus and rickets. Both iron and aluminum,¹ when given in excess of the total phosphorus, were shown to precipitate the alimentary phosphorus as insoluble phosphates which were not absorbed and consequently caused a lowering of the blood phosphorus in guinea pigs. When ferrie chloride² was added to a nonrachitogenic diet, it rendered this same diet rachitogenic for rats and a low serum phosphorus resulted. It was found that iron and ammonium citrates exerted the same effect and reduced iron acted similarly. The rachitogenic effect could be prevented by adding excess phosphorus to the diet. Deobald and Elvehjem³ pointed out that the addition of a soluble iron salt to the diet in chicks produced severe rickets within five days and that the lowering of the blood phosphorus to this degree might affect other biologic processes as well as bone nutrition. The clinical implications from these animal experiments are obvious, and the possible harm resulting from the administration of large doses of iron during the period of growth and development of a child has been suggested. Brock and Diamond² state that large doses of iron continued over a

long period of time in childhood might have an effect similar to that observed in experimental animals, perhaps not by the actual production of rickets, but by evidences of malnutrition of the bones. Elvehjem⁴ also warns of the danger of administering large amounts of iron and advises that the dose be kept at a minimum. With these points in mind balance studies were carried out on 19 adults to ascertain the effect of iron administration on phosphorus, calcium, and nitrogen retention.

METHOD

The method of study was the same as that described in the first of a series of reports on iron balances.⁵ Sixteen patients with varying degrees of hypochromic anemia, either idiopathic in origin or secondary to hemorrhage, and 3 control patients without anemia were selected for the study. The control period was preceded by a three-day adjustment period on the balance diet before observations were begun. Each balance period was of six days' duration, and the results are reported as the average value per day. During the control period the iron intake was obtained from the diet alone. In subsequent periods iron and ammonium citrates were given in varying amounts. Nitrogen was determined by the Kjeldahl method, phosphorus by the method of Fiske and Subbarow,⁶ and iron by the method of Reis and Chakmakjian.⁷ Calcium determinations followed the method of McCradden.⁸

The diets contained 1 Gm. of protein per kilogram of body weight, and the dietary iron intake varied from 9 to 12 mg. a day. The phosphorus and calcium intake, derived exclusively from the food, was approximately 1.5 and 1.3 Gm. a day, respectively.

RESULTS

A summary of the iron, phosphorus, calcium, and nitrogen balances for each patient is given by periods in Table I. The age of the patients, who were all females, varied from 21 to 53 years. An examination of the average daily balances during the control periods shows no correlation between the storage of the substances and the age of the patient. All patients except the controls (Cases 16, 17, and 18) had hypochromic anemia of varying degree. As has been pointed out previously, there is no correlation between the degree of anemia and the iron retention⁹ either during the control period or with the administration of medicinal iron, and in this study the degree of anemia had no effect on the phosphorus, calcium, or nitrogen balances.

In Table II is given a summary of the balance studies showing the intake and balance for each of the four substances during both the control period and the period of iron administration. The results during the administration of iron are expressed as the average daily intake and balance for the period of observation, which varied from six to forty-eight days, rather than being given by periods. It will be seen that during the period of iron administration all patients retained this metal, the amount retained varying with the intake. Cases 1 to 4 received small amounts of iron intramuscularly, 1.5 grains of iron and ammonium citrates a day. Cases 5 to 11 received from 15 to 36 grains of iron and ammonium citrates orally a day, and Cases 12 to 19 received 45 grains of the same preparation by mouth.

Control indicates state of balance for each substance: positive, negative, or in equilibrium. Subsequent periods with iron administration indicate increased or decreased retention as compared to control period regardless of actual state of balance.

pressed as positive, negative, or in equilibrium. The other columns show the increase or decrease in phosphorus storage as compared to the control period, a + sign indicating that more was retained than during the control period and a - sign indicating that less was retained even though the patient might still have been in an actual positive balance. It is seen that in the first period of iron administration 8 patients retained less phosphorus than in the control period and 11 retained more. In the second period 10 of the 17 patients retained less than during the control period and 7 retained more.

In the first 4 patients, who received small doses of iron intramuscularly, there are ten observation periods during iron administration and in four of these, all in one patient, there was a decrease in phosphorus retention. In the other six periods there was an increase of phosphorus retention over the control period. It will be noted in Case 4 that less phosphorus was retained in each of the four periods on iron therapy than during the control period, but the patient was still in a positive balance for each period (Table I) as well as in a positive balance for the entire observation period of twenty-four days (Table II). If the explanation for the diminished phosphorus retention in experimental animals is correct (a precipitation of insoluble phosphates in the alimentary tract), there would be no reason to expect that intramuscularly administered iron would affect the phosphorus balance and there is no evidence of such an effect in these cases.

In the second group of 7 patients (Cases 5 to 11) the iron was administered by mouth in moderate amounts, from 15 to 36 grains of iron and ammonium citrates a day. There are twenty-two balance periods during iron administration in this group, and in sixteen of these there was a decrease in phosphorus retention. In only six periods was more phosphorus retained than during the control period. This might seem to indicate that decreased phosphorus absorption and retention occurred, but when the results of the third group of patients who received larger amounts of iron are considered, the significance of the preceding group is lost. In the third group (Cases 12 to 19) 45 grains of iron and ammonium citrates were administered daily by mouth. In the twenty-seven periods of observation during iron administration, there were twelve in which there was a decreased retention of phosphorus and fifteen in which the retention was increased. Since this larger dose of iron did not decrease phosphorus retention, it seems doubtful whether the diminished retention in the preceding group of 7 patients was due to iron ingestion. There were a total of forty-nine observation periods during orally administered iron, and in twenty-one of these there was increased phosphorus retention and in twenty-eight a decreased retention.

In the entire group of 19 persons there were fifty-nine observation periods during iron administration, and in thirty-two of these periods less phosphorus was retained than during the control period, while in twenty-seven periods there was an increased phosphorus retention. There were 5 patients in actual negative phosphorus balance during iron administration, whereas there were 3 in negative balance in the control period. These results

are interpreted as indicating that there is no significant change in the retention of phosphorus in the adult as a result of the administration of iron either orally or intramuscularly. It is our impression that the tendency toward decreased phosphorus retention is too slight and too inconsistent to be of significance.

In Table III are presented in similar manner the effects of iron administration on the retention of calcium. In thirty-two of the fifty-nine balance periods there was a diminished calcium retention as compared to the control period; in twenty-five instances the retention was increased, and in two periods there was no change. These figures are almost identical with those obtained for phosphorus, but a comparison of the tables shows that in individual cases and periods there is no correlation between the phosphorus and calcium retention. In the twenty-five periods of increased calcium retention there was increased phosphorus retention in only fourteen and a diminished phosphorus retention in eleven. Of the thirty-three periods with diminished calcium retention only twenty-one also showed diminished phosphorus retention. In the ten observation periods during intramuscular iron therapy in the first 4 patients there are five periods with increased, and 5 with decreased, calcium retention. In the second group of 7 persons who received iron by mouth there are twenty-two observation periods. In nine of these the calcium retention was increased and in thirteen it was decreased. There were twenty-seven balance periods during iron therapy in the last 8 patients (Cases 12-19) who received larger amounts of iron. There were eleven periods with increased, and 14 with decreased, calcium retention, and two periods with no change from the control period. During the control period there were 9 persons with calcium balance and 9 persons who were in an actual negative calcium balance for the entire period of iron administration. These results indicate that iron administration does not significantly affect calcium retention.

Table III also contains data on nitrogen metabolism. It is seen that the administration of iron did not affect nitrogen retention, and that there is no correlation between the retention of nitrogen and the retention of either calcium or phosphorus.

SUMMARY

The phosphorus, calcium, and nitrogen balances of 19 adult patients were determined during the administration of medicinal iron. No consistent or significant changes in the metabolism of these substances could be detected during the administration of iron either intramuscularly or orally.

ALTERATION OF GLUCOSE TOLERANCE IN PATIENTS WITH DISEASE OF PITUITARY, THYROID, AND ADRENAL GLANDS BY CHANGES OF DIET*

JAMES A. GREENE, M.D., AND L. W. SWANSON, M.D.
IOWA CITY, IOWA

THE numerous reports of disturbance of carbohydrate metabolism in patients with dysfunction of the pituitary, thyroid, and adrenal glands, together with the development of this disturbance in experimental animals with altered function of these endocrine glands, appear to have definitely established a relationship between the function of these glands and carbohydrate metabolism. It has been shown also that alteration of the metabolic mixture through diet will produce changes in carbohydrate metabolism.¹ It is important in the proper treatment of patients and of academic interest to ascertain whether or not the alteration of such metabolism is due directly to dysfunction of these endocrine glands or to changes in the metabolic mixture. The present study was instituted to obtain data regarding this question. These data, which we recognize as incomplete, is submitted in hopes of arousing interest in the subject.

METHOD

Glucose tolerance curves were obtained in patients with acromegalia, pituitary dwarfism, hyperthyroidism, myxedema, Addison's disease, and paroxysmal hypertension due to a pheochromocytoma. The tolerance was ascertained in the morning after the patient had fasted for from twelve to fourteen hours. Blood samples were obtained from the finger tip before, one-half, one, one and one-half, two, and two and one-half hours after administration of 50 Gm. of glucose in aqueous solution orally. The metabolic mixture was then altered by change of diet for from three to twenty-four days and the glucose tolerance test was repeated. In all instances the tolerance curves were obtained after two types of diets, and in most cases after three. One diet was of a high carbohydrate and low fat content, another was of low carbohydrate and high fat content, and a third, of both the carbohydrate and fat content the same proportion as that in an

average hospital diet. The caloric value of the diets varied from patient to patient, but were approximately the same for all diets prescribed for any one patient.

FIG. 1.

FIG. 2.

It was not deemed necessary to administer a given amount of glucose per kilogram of body weight for measure of the glucose tolerance because curves of one patient were not compared with those of another, but only with those of the same patient under different dietary conditions.

Fig. 3.

Fig. 4.

Fig. 5.

Fig. 6.

RESULTS

It is to be noted from Table I, which lists the number of patients with each disease and the effect of dietary alterations upon the glucose tolerance curve, that the tolerance was altered in all cases except in one of hyperthyroidism, and the results were questionable in one of Addison's disease. Representative alterations produced in the curve of each disease are shown in the accompanying graphs. Acetone bodies were not demonstrable in any of the seven patients in whom this point was ascertained during high fat, low carbohydrate diets.

TABLE I

NO. OF PATIENTS	DISEASE	EFFECT UPON GLUCOSE TOLERANCE	
		ALTERED	UNALTERED
2	Pituitary dwarfism	2	0
1	Acromegalia	1	0
2	Myxedema	2	0
8	Hyperthyroidism	7	1
1	Addison's disease	?	0
1	Pheochromocytoma	1	0
Total 15		13	1

COMMENT

It is recognized that there are too few cases of pituitary and adrenal dyscrasia in our study to permit any conclusions, but the results suggest that the disturbed carbohydrate metabolism may be due in part, if not entirely, to alteration of the metabolic mixture. If this is true, the disturbed carbohydrate metabolism can be corrected by proper dietary measures.

In regard to dysfunction of the thyroid gland, sufficient data are available to justify certain conclusions. There is usually a diminished glucose tolerance, but hypoglycemia may occur. Our results show that the diminished tolerance in hyperthyroidism is due to alteration of the metabolic mixture and that it can be remedied by a high carbohydrate and high caloric diet. The one patient who failed to show alteration of the tolerance curve had an initial normal curve and it was not altered by such a diet. The glucose tolerance can be diminished in these patients by a high fat and low carbohydrate diet. The one patient who failed to show this response developed hypoglycemia after two and one-half hours, and a high fat and low carbohydrate diet for eleven days thereafter did not alter the curve. A high carbohydrate and high caloric diet, on the other hand, was followed by a flattening of the curve and elimination of hypoglycemia. The explanation for this was not clear until we observed spontaneous hypoglycemia in patients due to a high fat diet.² It appears, therefore, that a high carbohydrate and high caloric diet is indicated in all cases of hyperthyroidism regardless of whether or not there is a diminished glucose tolerance or a hypoglycemia.

These observations show that the disturbed carbohydrate metabolism in hyperthyroidism is due to alteration of the metabolic mixture and is not due directly to dysfunction of the thyroid gland. The results show, in addition, that it is important to correct this altered glucose tolerance in such patients dur-

ing the preoperative treatment and that the maximum improvement should be one of the criteria which indicates whether or not the patient is prepared for thyroidectomy.

The patients with myxedema react to alterations of diet in the same manner as do normal persons, and this indicates that the diminished thyroid secretion is not a factor in the changes in carbohydrate metabolism in these cases.

SUMMARY

The glucose tolerance has been altered in patients with dysfunction of the pituitary, thyroid, and adrenal glands following alteration of the metabolic mixture by changing the carbohydrate and fat content of the diet. The tolerance was improved with a high carbohydrate diet and diminished with a high fat diet. It is suggested that in hyperthyroidism the maximum improvement in glucose tolerance be obtained before thyroidectomy is advised.

THE COMPARATIVE IODINE CONTENT OF WHOLE BLOOD AND SERUM*

KARL P. KLASSEN, M.D., RUTH L. BIERBAUM, S.B., AND GEORGE M. CURTIS,
PH.D., M.D., COLUMBUS, OHIO

THE majority of patients with early, untreated exophthalmic goiter present an elevated blood iodine.¹ Veil and Sturm,² as early as 1925, demonstrated that there was an increase in the alcohol insoluble or "organic" iodine fraction in the blood of patients with hyperthyroidism. Later investigators have confirmed this observation.^{3, 4} This increased "organic" iodine *presumably* represents a greater circulation of the high iodine containing thyroid hormone or of its higher metabolic products.

The level of the "inorganic" fraction of iodine in the blood shows considerable variation.⁵ It is increased following the oral administration of inorganic iodine.³ A portion of the "inorganic" iodine represents the iodine of nutrition, i.e., iodine derived from the food, water, and, to a limited extent, air; and which enters the blood stream principally from the gastrointestinal tract, but also from the lungs. Normally this fraction should be small considering the relatively low daily intake of iodine.

We have observed that in patients on a low iodine intake analyses of the blood cells reveal only a trace of iodine, this being consistently increased by the

This investigation was aided by a grant from the Comly Fund for Research of the Ohio State University.
Received for publication, February 28, 1910.

oral administration of iodides. The present report deals with the results of a systematic investigation of the distribution of iodine in the serum and blood cells in patients without and with hyperthyroidism before and following the oral administration of iodine.

METHODS

The investigation was carried out on four groups of patients. The *first* group was composed of ten individuals without thyroid disease and the *second* of ten patients with exophthalmic goiter. These patients were maintained on the usual hospital diet which has a relatively low iodine content.⁶ They had not received iodine medication in any form for at least one month. The *third* group was made up of ten patients from the chest clinic, who had been lipiodolized for diagnostic purposes. No basal metabolic rate determinations were made on these patients; they showed no clinical evidence of thyroid disease. The *fourth* group was composed of ten patients with exophthalmic goiter who had received Lugol's solution or potassium iodide by mouth for from four to thirty days.

A sample of 70 c.c. of blood was drawn, with the patient in the fasting state. Twenty-five cubic centimeters of the blood were oxalated for the whole blood iodine determination. Forty cubic centimeters of blood were used to obtain from 15 to 25 c.c. of serum by clotting and centrifuging. Five cubic centimeters of blood were used for hematocrit determination. The analyses of the iodine in the whole blood and serum were made by the method of Matthews.⁷

TABLE I
IODINE CONTENT OF SERUM, BLOOD CELLS, AND WHOLE BLOOD

IODINE IN SERUM OF 100 C.C. OF WHOLE BLOOD (μ g)*	IODINE IN BLOOD CELLS OF 100 C.C. OF WHOLE BLOOD (μ g)	TOTAL IODINE IN SERUM PLUS CELLS OF 100 C.C. OF WHOLE BLOOD (μ g)	IODINE CONTENT OF 100 C.C. OF WHOLE BLOOD BY ANALYSIS (μ g)
4.2	0.2	4.4	4.2
5.0	0.4	5.4	5.2
35.0	2.3	37.3	38.1
924.0	203.0	1,127.0	1,058.0

*A microgram (μ g) equals 0.001 mg.

The percentage of iodine in the serum was obtained by the use of the following formula, in which I_b and I_s represent the concentration of iodine in the whole blood and serum, respectively, while the cell volume of the blood is expressed by V :

$$\text{Per cent of iodine in serum} = \frac{I_s (100 - V)}{I_b}$$

As a check on the accuracy of the analytical methods employed, the actual iodine content of the blood cells was determined in four patients. Following the removal of the serum by centrifuging, the blood cells were washed five times with normal saline and then analyzed by the usual method. Twenty cubic centimeters of packed cells were used. The results of this procedure are shown in Table I. The results obtained by analyses of the whole blood as compared to those by adding the separately determined iodine content of serum and blood cells show only a small deviation. The present method of iodine analysis is accurate to within 5 per cent for the amount of iodine ordinarily found in blood.

OBSERVATIONS

In the ten individuals without thyroid disease (Table II) the basal metabolic rate was within normal limits, averaging plus 5 per cent, with fluctuations of from minus 13 to plus 8. With a low iodine intake the whole blood iodine averaged 4.0 μg per cent, with variations of from 3.1 to 5.6 μg per cent. This is a normal blood iodine for this region by the present method of iodine analysis.⁷ The serum iodine concentration showed a similar variation. It ranged from 5.9 to 10.2, averaging 7.1 μg per cent. One hundred cubic centimeters of blood contained from 3.1 to 5.0 μg of serum iodine, with a mean value of 3.8 μg . The blood cells of 100 c.c. of whole blood contained only 0.2 μg of iodine, taking the average of all ten determinations. The serum iodine thus constituted, on the average, 95 per cent of the total iodine of the blood.

Averages		+ 5	4.0	7.1	46	3.8	95

The basal metabolic rate was elevated in the ten patients with exophthalmic goiter (Table III). The lowest basal rate was plus 39, the highest was plus 85 per cent, averaging plus 60 per cent. The whole blood iodine was increased in all ten patients, ranging from 5.5 to 15.7 μg per cent. The average of 10.0 μg per cent was two and a half times greater than the normal blood iodine. The serum iodine showed a similar elevation, fluctuating from 10.4 to 25.0 μg per cent in these patients with exophthalmic goiter. The average was 18.0 μg per cent as compared with 7.1 in the patients without thyroid disease. The serum of 100 c.c. of whole blood contained from 5.3 to 14.7 μg of iodine, averaging 9.6 μg . The blood cells of the same amount of whole blood contained only 0.4 μg . In these patients 95 per cent of the whole blood iodine was in the serum.

In the ten patients without thyroid disease, but who had been lipiodolized, the whole blood and serum iodine reached an unusually high level (Table IV). This increased blood iodine was due to the high absorption of the iodine of the lipiodol from the gastrointestinal tract. Fluoroscopy following lipiodolization revealed the presence of lipiodol in the stomach in all cases. The absorption from the bronchial tree is low, as has been shown in a previous report.⁸ The whole blood iodine ranged from 18.5 to 3153.0 μg per cent, with a serum iodine concentration of from 25.7 to 4232.0 μg per cent. The serum of 100 c.c. of whole

blood contained from 11.3 to 2455.0 μg of iodine. There was an absolute, as well as a relative, increase in the corpuscular iodine, the cells of 100 c.e. of blood containing from 7.2 to 698.0 μg of iodine, or from 12 to 39 per cent of the total blood iodine.

Although the total iodine concentration in the patients with exophthalmic goiter who had received iodine in the form of Lugol's solution or potassium iodide was not as high as in these lipiodolized, the percentage of iodine in the serum to the total blood iodine was approximately the same (Table V). The basal metabolic rates were lower than in the patients with exophthalmic goiter not on iodine medication, and averaged plus 35 per cent, ranging from plus 8 to plus 60. The lowest whole blood iodine was 15.2 and the highest was 107.0 μg per cent. The iodine of the serum showed a corresponding increase, ranging from 20.2 to 130.0 μg per cent. The serum of 100 c.e. of whole blood contained from 12.2 to 63.7 μg , or on an average, only 72 per cent of the total blood iodine. The blood cells of the same amount of whole blood contained from 3.0 to 43.3 μg of iodine, as compared with 0.4 μg in the patients with exophthalmic goiter but not on iodine medication.

DISCUSSION

The increased whole blood iodine in the patients with untreated exophthalmic goiter as compared with the normal blood iodine of the individuals without thyroid disease was due to the higher iodine concentration of the serum, and not to an increased iodine content of the cells. With a low iodine intake the corpuscular iodine was approximately the same in both conditions. It constituted, on an average, only 5 per cent of the total blood iodine. The iodine concentration of the cells was thus similar to that of the cerebrospinal fluid of patients both with and without hyperthyroidism, as previously reported.⁹ The average cerebrospinal fluid iodine concentration was found to be 0.5 μg per cent, as compared with the average corpuscular iodine concentration of 0.6 μg per cent in the twenty patients on a low iodine intake.

The corpuscular iodine would appear to represent the diffusible iodine fraction of the blood, and, we may assume, also a part of the nutritional iodine of the blood. An increased intake of iodine is followed by an increase in the diffusible iodine fraction of the blood, as evident by the higher corpuscular iodine concentration. However, this corpuscular iodine represents only a part of the nutritional iodine, as there is also a concomitant rise in the serum iodine content. A portion of the ingested iodine is diffusible, while the remaining part is retained in the serum.

The actual amount of iodine ingested by these patients was not determined. No attempt has been made to demonstrate a quantitative relationship between the iodine intake and the nutritional iodine concentration of the serum and cells.

The determination of the whole blood and serum iodine is of some practical value in the differential diagnosis of hyperthyroidism in that it makes possible the demonstration of an increased amount of diffusible iodine in the blood. An elevated whole blood iodine may be due to the increased serum iodine of hyperthyroidism, but may also be caused by an elevated nutritional iodine, brought about by the ingestion of high iodine content foods or the administration of

iodine. The finding of a high corpuscular iodine concentration indicates that the patient under consideration has received iodine medication, and that this is responsible for the elevated whole blood iodine.

SUMMARY

In ten individuals without thyroid disease and maintained on a low iodine diet; with normal metabolic rates and normal whole blood iodine averaging 4.0 μg per cent, the average serum iodine was 7.1 μg per cent. The serum iodine constituted, on an average, 95 per cent of the total blood iodine.

In ten patients with exophthalmic goiter, with an average basal metabolic rate of plus 60 per cent, and maintained on a low iodine intake, the average blood iodine was 10.0 μg per cent, the average serum iodine was 18.0 μg per cent. On an average, 95 per cent of the iodine of the blood was in the serum.

Following lipiodolization of ten patients without thyroid disease, the whole blood iodine ranged from 18.5 to 3153.0 μg per cent, with the serum iodine fluctuating from 25.7 to 4,232.0. From 61 to 88 per cent, or on an average 75 per cent, of the total iodine of the blood was in the serum.

In ten patients with exophthalmic goiter, with an average basal metabolic rate of plus 35 per cent, while receiving Lugol's solution or potassium iodide by mouth, the blood iodine concentration fluctuated from 15.2 to 107.0 μg per cent, with the serum iodine concentration varying from 20.2 to 130.0. From 60 to 80 per cent, or at an average 72 per cent, of the iodine of the blood was in the serum.

CONCLUSIONS

In individuals without thyroid disease and with a normal blood iodine, and also in those patients with exophthalmic goiter with an elevated blood iodine while on a low iodine intake, an average of 95 per cent of the total iodine of the blood is in the serum.

The elevated blood iodine of patients with exophthalmic goiter is due to an increased amount of serum iodine.

Following the oral administration of varying amounts of iodine or lipiodolization, there is an increased corpuscular iodine concentration, with a relative fall in the serum iodine to an average of 74 per cent of the total iodine of the blood.

WALTER J. SIEBERT, M.D., AND FREDERICK LOOSE
St. Louis, Mo.

RECENT studies² of a solution of sulfanilamide† demonstrated that in the guinea pig and rabbit higher blood-free sulfanilamide concentrations are obtained with the solution than when sulfanilamide is given in equivalent dosage in other forms. Furthermore, the sulfanilamide appears in the blood more quickly when given as the solution, and its rate of elimination is not accelerated. The solution employed was essentially a mixture containing in each fluidounce approximately 30 grains of sulfanilamide in glucose, glycerin, and sodium lactate.

The question has arisen as to whether the sulfanilamide in the solution would be absorbed as rapidly as an equivalent amount of drug in the dry form, because of a possible linkage with the glucose of the solution. It has been postulated, also, that in persons with partial or complete achlorhydria and rapid gastric emptying time the sulfanilamide, if bound to glucose in the solution, might not be absorbed as quickly or as completely as when administered in dry form.

To answer these questions studies were made, employing the solution of sulfanilamide in glucose, glycerin, and sodium lactate, and for comparison a brand of sulfanilamide tablets accepted by the Council on Pharmacy and Chemistry of the American Medical Association. The subjects were five males and one female between the ages of 21 and 49 in apparent good health, and one male, 49 years old, and one female, 51 years old, both of whom were afflicted with pernicious anemia.

Vitamin C determinations were made whenever possible for the purpose of trying to establish some correlation between vitamin C gain or loss and the sulfanilamide concentration. While these cases are not sufficient to draw any conclusions, there is enough evidence of such correlation to warrant further investigation.

Quantitative determination of blood sulfanilamide was made according to the method of Bratton and Marshall.¹ Since a comparison was being drawn between free sulfanilamide and a solution which might possibly contain the drug in a conjugated form, all values given are in terms of free sulfanilamide. Total sulfanilamide, that is, free plus conjugated, was not determined.

*From the Department of Pathology, De Paul Hospital, St. Louis.

Received for publication, May 24, 1940.

†The solution of sulfanilamide known as "solution of sulfanilamide in glucose, glycerin, and sodium lactate," was furnished through the courtesy of Donley-Evans & Co., St. Louis.

PROCEDURE AND RESULTS

The first patient was a white male, aged 26 years, weighing 190 pounds. At the beginning of the study his red blood cell count was 4,140,000; hemoglobin, 13.8 Gm. (Newcomer method); white blood cell count, 9,600; nonprotein nitrogen, 40 mg. per cent; blood sugar, 92 mg. per cent; blood vitamin C, 0.15 mg. per cent. Fifteen cubic centimeters of the solution of sulfanilamide (equivalent to 15 grains of sulfanilamide) was administered every four hours. Sulfanilamide determinations were carried out on the blood at approximately 25° C. one-half hour before the drug was given and at four-hour intervals thereafter. The results are shown in Table I.

The nonprotein nitrogen immediately following this study was 40 mg. per cent; the blood sugar, 87 mg. per cent. The blood picture showed no changes.

In this series of observations the same patient was used as in the first study, but after a period of two weeks. At this time, the nonprotein nitrogen was 42 mg. per cent, and the blood sugar was 87 mg. per cent. Blood vitamin C was 0.13 mg. per cent immediately before and 0.04 mg. per cent immediately following the experiment. Fifteen cubic centimeters of the solution of sulfanilamide was administered every four hours; sodium bicarbonate (approximately 20 to 30 gr. every two hours) was given throughout the test period in sufficient quantity to keep the urine alkaline during that time. Sulfanilamide determinations were made on the blood one-half hour before each dose of the drug was administered. The results are given in Table III.

The second patient was a white male, aged 30 years, weighing 194 pounds. At the start of the experimental period his red blood cell count was 4,870,000; hemoglobin, 15.1 Gm. (Newcomer method); white blood cell count, 8,400; nonprotein nitrogen, 24 mg. per cent; blood sugar, 81 mg. per cent. A blood vitamin C determination was not done at this time, but several days later the blood vitamin C was 1.73 mg. per cent. Fifteen cubic centimeters of the solution of sulfanilamide (equivalent to 15 grains of drug) was administered every four hours. Blood sulfanilamide determinations were made at approximately 25° C. one-half hour before each dose of the solution was administered. The results obtained are shown in Table IV.

A period of one week elapsed between the close of this and the following series of observations. The nonprotein nitrogen immediately preceding this series was 26 mg. per cent, and immediately following, 28 mg. per cent. Blood sugar determinations were not

made at this time. There were no significant hematologic changes. A dose of 15 grains of the brand of sulfanilamide tablets (5 gr.) previously employed was administered every four hours as shown in Table V.

The third patient was a white male, 28 years old, weighing 181 pounds. His red blood cell count immediately preceding the observations was 4,070,000, with a Newcomer hemoglobin of 15.6 Gm.; the white blood cell count, 6,500; the nonprotein nitrogen, 29 mg. per cent; the blood sugar, 72 mg. per cent.

Neither the white blood cell count nor the hemogram showed any appreciable change subsequently. The blood vitamin C three days before the study was started was 1.47 mg. per cent as determined with a photoelectric adaptation of Ingall's method for blood vitamin C. Fifteen cubic centimeters of the solution of sulfanilamide (equivalent to 15 grains of drug) was administered every four hours. Sulfanilamide determinations at 25° C. were made on the blood one-half hour before each dose of the drug was administered. Concurrently, carbon dioxide combining power of the blood was determined as shown in Table VI.

A period of one week was allowed to elapse between the foregoing and the following series. The nonprotein nitrogen immediately preceding was 27 mg. per cent, and immediately following, 28 mg. per cent. Neither blood sugar nor vitamin C determinations were done at this time. The hemogram and red and white blood cell counts were essentially the same as at the beginning of the series. Fifteen grains of the previously employed brand of sulfanilamide tablets were administered every four hours. As before, sulfanilamide determinations were made on the blood one-half hour before each dose of the drug was administered. Results are shown in Table VII.

A white male, aged 49 years, weighing 185 pounds, who for the past five years had been under treatment for pernicious anemia, was the subject in the fourth study. During the preceding eight months he had received no hydrochloric acid and only parenterally administered liver extract. Just before the experimental observations his red blood cell count was 4,010,000; Newcomer hemoglobin, 11.1 Gm.; white blood cell count, 7,300. The nonprotein nitrogen was 35 mg. per cent, and the blood sugar was 93 mg. per cent. Fifteen cubic centimeters of the solution of sulfanilamide were administered every four hours. Sulfanilamide determinations were made on the blood one-half hour before the drug was given. Immediately following the last sulfanilamide determination the stomach contents showed free nor combined hydrochloric acid. The results obtained are given in Table VIII.

*Further observations were not possible because the patient found it necessary to leave the hospital.

The subject in the fifth study was a white female, 24 years old, weighing 105 pounds. At the start of this experiment she had a red blood cell count of 4,060,000, a hemoglobin of 11.6 Gm. (Newcomer method), and a white blood cell count of 6,200; her hemogram at

this time was essentially normal. Her nonprotein nitrogen, blood sugar, and urinalysis were well within the normal limits both before and immediately following the experiment. An arbitrary dose of 60 c.c. of the solution of sulfanilamide per day was administered in divided doses, 10 c.c. every four hours. Sulfanilamide determinations were done on the blood one-half hour before the drug was administered. All determinations were done immediately at approximately 25° C.

In the sixth study the subject was a white male, 41 years old, weighing 138 pounds. At the start of this experiment he had a red blood cell count of 4,320,000, a hemoglobin of 14.3 Gm. (Newcomer method), and a white blood cell count of 9,100. His hemogram was normal, his nonprotein nitrogen was 27 mg. per cent, his blood sugar was 82 mg. per cent, and his vitamin C determination was 1.13 mg. per cent; a basal metabolism run three weeks prior to this test was plus 23. A dose of 60 c.c. of the solution of sulfanilamide a day was administered in divided doses, 10 c.c. every four hours. Determinations were done as previously.

A period of one week was allowed to elapse between the close of this series and the beginning of the next study. A dose of 60 grains a day of a brand of sulfanilamide tablets (5 gr.) accepted by the Council was administered in divided doses as before. The blood chemistry and hematology of this subject showed no significant changes from those run before the experiment with the exception of the vitamin C determination, which was

0.72 mg. per cent. The individual in the seventh study was a 21-year-old white male weighing 149 pounds. His red blood cell count immediately preceding this experiment was 4,720,000, with a Newcomer hemoglobin of 15.8 Gm. His white blood cell count at this time was 7,600, and his hemogram was normal. His nonprotein nitrogen was 26 mg. per cent, his blood sugar was 92 mg. per cent, and his vitamin C determination was 1.26 mg. per cent. A dose of 60 c.c. of the solution of sulfanilamide a day was administered in divided doses. Sulfanilamide determinations were done on the blood one-half hour before each dose of the drug was administered. All determinations were done immediately and at approximately 25° C.

The blood chemistry showed no significant changes at this time over that preceding this experiment; the red blood cell count and hemoglobin were approximately the same; the white blood cell count was 4,800, with a normal hemogram.

A period of one week was allowed to elapse between this experiment and the following study. The patient's blood chemistry immediately preceding this experiment was essentially the same as previously. The white blood cell count was 9,200. Sixty cubic centimeters of sulfanilamide solution, with concomitant dosages of sodium bicarbonate, were administered as previously.

TABLE XV

SOLUTION SULFANILAMIDE IN GLUCOSE, GLYCERIN, AND SODIUM LACTATE

8 P.M.	10 gr.	1.3	Alkaline
12 midnight	10 gr.	1.5	Alkaline

Tests were discontinued because of patient's refusal to cooperate further.

The individual in the eighth study was a white female, aged 51 years, weighing 109 pounds, who for nine years had been under treatment for pernicious anemia. At this time, her red blood cell count was 3,940,000, with a Neweomer hemoglobin of 12.2 Gm. Her white blood cell count was 6,600, with a normal hemogram. The nonprotein nitrogen and blood sugar values were well within the normal limits. A basal metabolism run five weeks prior to this test was plus 9. A modified G-I series showed a rather marked increase in stomach motility, and the gastric analysis showed a total achlorhydria.

An arbitrary dose of 60 c.c. of solution of sulfanilamide a day was administered in divided doses every four hours (10 c.c.). Sulfanilamide determinations were made on the blood one-half hour before the drug was administered. At the close of this experiment, a nasal tube was passed and the gastric analysis still showed a total lack of free and combined acid. At this time this test was discontinued because the patient felt dizzy and complained of a headache; the following day, although she refused further laboratory studies, she reported that these symptoms had all disappeared.

10 P.M.		2.3

DISCUSSION

The results obtained in this study are summarized graphically in Table XVII. It will be seen that the maximum concentration of sulfanilamide attained in the blood in every case was higher when the drug was given in the form of the solution. With sulfanilamide tablets, excretion time was shorter, and the per cent loss of blood carbon dioxide combining power was greater.

In the face of a known, persistent, complete achlorhydria, a rise in blood sulfanilamide, comparable to that obtained in normal subjects, occurred when the drug was administered in the form of a solution.

When the solution of sulfanilamide was administered, together with large doses of sodium bicarbonate (20 to 30 gr. every two hours), no interference with absorption of the sulfanilamide occurred.

TABLE XVII

SUBJECT			TOTAL SULFANILAMIDE ADMINISTERED	MAXIMUM CONCENTRATION REACHED (MG.%)	TIME FOR EXCRETION (HOURS)	CO ₂ AT START (VOL. %)	CO ₂ AT MAXI- MUM CONEN- TRATION (VOL. %)	CO ₂ AT FINISH (VOL. %)	PERCENTAGE OF LOSS IN GLY- CEME FROM START TO MAXIMUM CONC.

†Pernicious anemia, five years. Stomach contents showed neither free nor combined hydrochloric acid.

‡Pernicious anemia, nine years. Marked high motility. Gastric analysis showed total achlorhydria before and after this experiment.

CONCLUSIONS

In the human subject higher blood concentrations of free sulfanilamide are obtained when the drug is given as the solution than when administered in equivalent dosage in the form of tablets.

The rate of elimination of the sulfanilamide is no more rapid when given as the solution than when administered in other forms.

The loss of blood carbon dioxide combining power is less when the solution of sulfanilamide is administered than when the drug is given in tablet form.

Even in the face of a persistent, complete achlorhydria, a rise in blood concentration of sulfanilamide comparable to that seen in the normal subject is attained when the drug is administered in the form of the solution. Hence the influence of gastric hydrochloric acid is not required to permit absorption of the sulfanilamide into the blood stream. If a linkage between the glucose and sulfanilamide does exist, gastric acidity is not needed for its breakdown.

LABORATORY METHODS

GENERAL

SIMULTANEOUS ARTERIAL AND VENOUS BLOOD CULTURES*

MAYNARD MURRAY, M.D., AND FRANK MOOSNICK, B.S.
CINCINNATI, OHIO

IN REVIEW of the literature on blood cultures one is impressed by the fact that a comparative study of the efficiency of arterial blood cultures as compared to venous is wanting. In cases of septicemia it is not uncommon to see petechial hemorrhages follow the distribution of a small artery. Because of these facts such a comparative study was conducted on 27 patients with clinical evidence of bacteriemia.

Fig. 1.

After surgical cleansing of the parts blood cultures were taken simultaneously from the cubital vein and from the femoral artery. The medium used was nutrient brain broth. The cultures were incubated at 37° C. for six days and subcultures were taken. The blood taken from each source was about 5 c.c. half of which was cultured aerobically and the other half anaerobically. As seen in Fig. 1 the results are as follows:

From 27 cultures taken from as many patients 15, or 55 per cent, were positive. In the 15 positive cases 14 were positive in the arterial culture, while only 6 were positive in the venous culture. One patient showed a positive venous culture and a negative arterial culture. As to the distribution of aerobic and anaerobic cultures, 15 aerobic and 7 anaerobic cultures were positive. One culture was positive in the anaerobic tube and negative in the aerobic tube.

From this experiment it is evident that arterial cultures are positive in a higher percentage of cases than are cultures taken from a vein.

A SIMPLIFIED APPARATUS FOR CONSTANT RATE INJECTIONS*

ALFRED E. KOEHLER, M.S., PH.D., M.D., SANTA BARBARA, CALIF.

IN STUDYING the ability of the animal body to utilize, store, or eliminate a substance injected intravenously, it is desirable to give it at a constant rate over a sufficiently long period of time, so that the organism can adapt itself and establish, if possible, an equilibrium. Similarly, in studying the effect of a substance such as a hormone upon the animal organism, the true response can usually better be evaluated if such a substance is given at a constant rate approaching physiologic or pathologic secretion.

Besides affording adequate time for diffusion and distribution equilibrium, continuous injection has the particular advantage over a single injection in that it frequently permits the observation of the change in equilibrium or response that may take place during the course of administration. Thus, if glucose is injected intravenously at a constant rate, the rapidity of disappearance of glucose from the blood stream constantly changes as the mechanism for sugar utilization becomes stimulated or, as in the case of the diabetic organism, first stimulated and then depressed. Similarly, if epinephrine is injected at a constant physiologic rate for two or four hours the blood pressure response may be quite different for the consecutive half hour intervals, in fact, may change from a pressor to a depressor effect. This difference of adaptation is often of primary importance and may be completely missed by a single injection even if prolonged to one-half hour.

APPARATUS FOR INJECTION

Several types of apparatus for constant rate injections that have been satisfactory for specific purposes have been described. One of the first motor driven pumps was described by Bock¹ in 1907, and modifications have been made by Friedman² (1910) and many others. Considerable improvement was, however, made in compactness, mechanical precision, and adaptability by Woodyatt³ in an apparatus described in 1917. This machine, as originally described, was subject to current fluctuations; due to the valvular mechanism involved, it never became popular for clinical use.

The apparatus to be described, although not capable of injection over indefinite periods as is the case with the Woodyatt pump, offers a simple, accurate means of constant rate injection, particularly practical for routine clinical tolerance tests. Our experience has shown that the average subject or patient cannot lie longer than two and one-half to three hours for injection without becoming unduly restless or uncomfortable, and consequently an apparatus for longer injection is usually not needed.

*From the Sansum Clinic and Santa Barbara Cottage Hospital, Santa Barbara.
Received for publication, November 29, 1939.

DESCRIPTION OF APPARATUS

Fig. 1 shows the front and side views of the apparatus. It consists essentially of a vertically supported syringe of 200 c.c. capacity or less that is actuated by a constant speed motor. The platform is about $7\frac{1}{2}$ inches square, and the two front corners support rigidly 2 steel tubes $\frac{5}{8}$ by 18 inches, $5\frac{1}{8}$ inches apart center to center. Sliding on these tubes are the stationary but adjustable support

Fig. 1.

for the bottom of the barrel of the syringe and also the screw actuated head which clasps the top of the plunger. Inside of each stationary vertical support and parallel to it is a screw supported by a bearing in the top cross bar and also by a bearing in the base plate through which it extends. The screw shaft is $\frac{1}{2}$ inch diameter with 13 threads per inch. The head carrying the plunger

carries two split nuts which engage with the screws. Spring tension keeps the split nuts together to engage the thread, but pressure on the clip extensions with forefinger and thumb of each hand disengages the head so that it can be freely moved up or down on the outside supports.

The two screws are synchronously turned beneath the top plate of the base by sprockets and chain connected to the motor drive which extends through the base plate from above. The sprockets at the base of the screws are 2 inches in diameter with 20 teeth, and the sprocket on the motor drive extension shaft has 10 teeth.

A constant speed motor of 50 cycle 1,500 revolutions, $\frac{1}{10}$ horsepower, synchronous type with a 1:1,120 reduction drive extending downward is mounted on the back portion of the base.* Mounting the motor on a rubber base and inserting a rubber disk universal drive in the power extension minimizes vibration and noise.

The above type motor and reduction drive ratios result in the delivery of 100 c.c. per hour with the type of 200 c.c. syringe we have used.

An automatic shut-off switch operated when the syringe plunger is down is essential. The switch is mounted on the lower barrel support and is operated by a rod that extends up through an extension of the movable head. An adjustable collar fastened on the rod is engaged when the head has moved down sufficiently. The mounting of the switch on the lower movable support serves to maintain a constant shut-off relationship regardless of the position of the support.

Obviously, any rate of delivery can be obtained by using different drive sprocket ratios or by the introduction of various gears. Adjustable 3 or 4 speed transmissions can be built in below the base. On the other hand, we have found it desirable to make the driving mechanism as simple as possible so as to avoid mistakes.

To vary the amount of a substance to be injected it has in general proved more satisfactory to change the concentration of the solution rather than change the rate of injection of the solution. Thus glucose can be given at the rate of 10, 25, or 50 grams per hour by using a 10, 25, or 50 per cent solution injected at the rate of 100 c.c. per hour. Epinephrine or insulin can be diluted with normal saline, so that any desired amount can be given per hour.

The main advantage of this type of apparatus is its simplicity and practicability, so that it can be used for routine bedside work. The standard syringe and tubing can, of course, be easily sterilized.

A SIMPLE PHOTOSTATIC CAMERA

ROBB SPALDING SPRAY, PH.D., AND ALFRED REEVES STANLEY, PH.D.
MORGANTOWN, W. VA.

PHOTOSTATIC records of books, journals, or other documents are a matter of great convenience and importance, especially where reprints are no longer available, or where library loans do not allow time for abstracting or for translation of foreign texts. "Bibliofilms" now provide a fairly convenient source of such records.

To meet daily desires, we have designed and built a photostatic camera of such simplicity and general utility that it seems suitable to present its details in such form that others may reproduce it. This device prints directly upon photographic paper, 5 by 7 inches, with only a slight reduction in size of text, in sharp white type upon a solid black ground. Even the finest types are sharply and legibly reproduced. Apart from the initial cost, prints may be made in quantity at approximately 2 cents each.

The apparatus consists of a baseboard with vertical grooved standards to support a camera, with its plate holder removed, on an adjustable slide. Fitted tightly above the camera is a light-proof horizontal box carrying a mirror at 45° angle, centered on the camera lens. The mirror is necessary to re-reverse the normally reversed image. Fitted into this box is a movable frame designed to receive an Eastman printing frame, 5 by 7 inches, fitting into a recess $\frac{3}{4}$ inch deep.

This movable frame is supported on a shelf attached to the camera slide, and is arranged to slide into or out of the mirror box, allowing $1\frac{1}{2}$ inches play for focusing. Guide strips and a wing-nut bolt to lock in focus are provided.

Three focusing movements are thus available: (1) the camera bellows; (2) the vertical movement of the camera slide; (3) the horizontal movement of the printing frame carrier. By proper manipulation of these movements all ordinary journal and book pages can be quickly reduced and sharply brought to focus on a 5 by 7 inch ground-glass screen.

The apparatus is easily constructed, chiefly of three-ply wood, conveniently available in large sheets. Bracing consists chiefly of 1 by 1 inch strips. Glue, wire brads, and $\frac{1}{8}$ inch wood screws are applied as indicated. The construction details are given in the illustrations and key to details. Basic dimensions alone are given.

We are using a Folmer and Schwing camera, 4 by 5 inches, as provided by Spencer Lens Co. (1924 catalog, No. 640, page 71). This is a speed graphic bellows camera with Kodak ball-bearing shutter and a 4 by 5 R. R. lens.

For illumination of books in photographing we use two Westinghouse par-38 projection flood bulbs, 150 watt, 120 volts. These are supported in clamps on metal standards at about 18 inches from the book, directed downward at

about 45° angle. With this illumination the exposure time runs around ten to twelve seconds, according to the selected printing paper.

From a variety of papers tested we have chosen Eastman Kodakline Bromide, single weight, smooth, semimatte, white paper. However, there is now available a new Kodabrom, grade A4, single-weight paper which promises even better contrast. We have not yet tried this new line, but from our experience with single-weight Kodabrom F4 paper we believe that this may be recommended.

Fig. 1.—A, $\frac{1}{4}$ inch three-ply baseboard, 30 by 14 inches, supported on 1 by 1 by 30 inch runners (A1); B, $\frac{1}{4}$ inch three-ply gusset brace, $11\frac{1}{2}$ by $12\frac{1}{4}$ inches, supporting C-C through 1 by 1 by $3\frac{1}{2}$ inch strips (E1); C-C, $\frac{1}{4}$ inch three-ply support standards, 34 inches long, constructed of two $\frac{1}{4}$ by 3 by 34 inches and one $\frac{1}{4}$ by $1\frac{1}{2}$ by 34 inches, separated by two strips of cardboard (C1), to form groove for slide D; drilled with a series of $\frac{1}{8}$ inch holes for vertical adjustment of slide D; C2, two $\frac{1}{4}$ by 2 by $10\frac{1}{4}$ inch bracing strips to support C-C; D, $\frac{1}{4}$ by 6 by $10\frac{1}{4}$ inch slide for camera support; drilled with two $\frac{5}{16}$ inch holes to fit camera connection holes, and ends perforated by a series of $\frac{1}{8}$ inch holes to fit similar spacing on standards C-C. Slide D held in position at desired elevation by two 6-penny casing nails. Camera attached to slide D by knurled bolts provided with camera outfit: E, Spencer Photographic Camera (1924 catalog No. 640) supporting projection tunnel F, and clamped to it by four heavy rubber bands and wire hooks; bands looped over four brads on top of F; F, Projection tunnel, $\frac{1}{4}$ inch three-ply, 8 by 6 by 7 inches, holding G, silvered clear glass mirror, smooth and free of striations, $7\frac{1}{2}$ by $6\frac{1}{2}$ inches, set at exactly 45° angle, and held in place in F with small glued wood blocks; H, Focusing tunnel, fitting snugly into F, and movable on shelf I; H2, Collar built onto H, to hold standard 5 by 7 inch printing frame, and movable on shelf I to a depth of $\frac{3}{4}$ inch. Tunnel H allows $1\frac{1}{2}$ inch sliding insertion into F for focus. Tunnel H is guided in groove on shelf I by slide H1 ($\frac{1}{4}$ by 2 by $5\frac{1}{4}$ inches). Slide H1 has a 3 by $\frac{1}{4}$ inch slot to match slot on shelf I, fitted with $\frac{3}{16}$ by 1 inch bolt and wing-nut to lock H at proper focus; I, Shelf, $\frac{1}{4}$ by $7\frac{1}{2}$ by 8 inches, with two $\frac{1}{4}$ by 2 by 6 inch strips (I1) to form slide for H1; provided with 3 by $\frac{1}{4}$ inch slot to match H1.

Developing, Fixing, and Drying Details.—

1. Eastman developer, formula D-72 (about one minute).
2. Acid rinse bath (48 e.c. of 28 per cent acetic acid to 1 liter of water) (five to six seconds).

3. Eastman fixing bath, formula F1 (ten to fifteen minutes).

4. Wash at least thirty minutes in running water, or preferably until hypo test is negative (hypo test formula HT-1a). Note: Eastman chemicals are used throughout.

5. Prints are rolled and dried slowly on Ferrottype squeegee plates which are treated with "Peep-o-Day" squeegee paste (Karika Mfg. Co., Yale, Okla.), obtained through Eastman stores.

Printing suggestions.—Books or journals are laid flat on the baseboard A. The selected page is pressed flat under a clear sheet of window glass. The back of the book is bent out and held against a triangular rack (not illustrated) with sliding wire hooks to hold back the loose pages.

Printing frames are loaded and prints developed under the light of a Kodak safelight lamp, using a series OA Wratten safelight.

In printing a continuous series of pages we load and print six frames. With two persons working, one loads the frames, turns the pages, and manipulates the shutter; the other adjusts the focus, holds the printing frames in place, and operates the illumination switch. Working together, pages may be printed in a series at a rate of a little less than one per minute.

Complete reprint series are then conveniently bound with an Ace "pilot" stapler.

NOTE: Since the acceptance of this article for publication, we have found it more rapid to omit the use of plate holders. A glass plate is fixed in the collar (H2) and print paper is faced to the glass and held during printing by a felt-faced board. The printing speed is thus almost doubled.

AN OPEN RACK FOR THE SYRINGE OUTFIT WHEN IN USE

JOSEPH L. SZEKELY, M.D., FLUSHING, N. Y.

NEXT to the stethoscope, the syringe is probably the most frequently used medical instrument today. Yet the vast improvement that took place in the technical armamentarium during the last few decades has neglected to provide a commercially available, adequate solution to the simple, every-day problem of where to rest the sterile syringe outfit while in use. Before and after filling a syringe with the solution, and while it is being taken to the patient, the outfit should be placed in a secure position and the sterility of the needle and the withdrawn parts of the plunger should be safeguarded. This is somewhat difficult. The rolling tendency and the fragility of the syringe are a handicap. Various makeshift arrangements are resorted to, such as putting a piece of cotton on the tray under the tip of the syringe, placing the syringe with the needle extending over the edge of the table or tray, or even in an ash tray, etc. The disadvantages, such as the hazard of contamination, the bending of the needle point, and the possibility of breaking the syringe, are obvious and often happen.

The device described here answers this problem. It is a flat steel rack supported by two cylindrical legs with either one or three resting places for a

Fig. 1.

corresponding number of syringes. It is called the Steri-Rack and is made in three models. The small model will rest one syringe; the medium and the large, up to three syringes. The resting places have the shape of a semicircle that broadens out into a wide open V. The syringe outfit is usually placed in a slanting position with the hub of the needle or the tip of the syringe in the semicircle and the other end on the table or tray. The semicircle will just take the medium part of the hub of the needle. The front and rear prominences of the hub cannot pass through this opening; hence the syringe will not slip off the rack easily. If the needle happens to have a hub varying from the conventional style, the part of the syringe tip right behind the hub will rest in the semicircle with the same effect. Both glass and metal tipped syringes can be rested on the rack whether a needle is attached or not. The height of the resting levels varies to suit the different size syringes (Fig. 1).

Fig. 2.

The V-shaped part of the resting place will take the barrel or the end of the plunger when a syringe is rested on two racks simultaneously (Fig. 2). The front end of the syringe outfit, either the hub or the barrel, rests on one rack, and the rear part, either the barrel or the end of the plunger, on another. Two different racks or two of the same model can be paired. The various heights of the semicircular and V-shaped resting places complement each other. This makes it possible to rest in a balanced position one or two of any size syringe, from the smallest up to a large metal ear syringe with both ends supported. Such an arrangement is advantageous, for instance, where prolonged sterility must be maintained or the barrel has a protruding side part, like that on a venoclysis syringe. The raised bottom line and the cylindrical legs, proportionate in length to the height and width of the rack, insure stability. The device is made throughout of stainless steel.

GONOCOCCUS COMPLEMENT FIXATION TEST

ALBERT M. DI GIOIA, A.B., SAN FRANCISCO, CALIF.

IN 1911, Schwartz and McNeal emphasized the necessity of using polyvalent antigens* in the gonococcus complement fixation tests because they believed the gonococcus belonged to a heterogeneous family. Until now, except for various research investigators, interest in the test has waned for the following reasons: first, the test would give no information in known acute or subacute cases; second, most laboratories were unable to obtain suitable antigens and positive controls; third, irregularities in the performance of the test. After a study of over 800 blood samples in this laboratory, we have attempted to eliminate some of the difficulties in the performance of the test. As a result, our experiences have been gratifying.

The following technique of the test is similar to that of Kolmer with certain modifications by this laboratory:

Solutions and Reagents.—

1. 0.85 per cent sodium chloride in distilled water.
2. 2 per cent sheep cells, defibrinated or citrated.
3. Anti-sheep hemolysin, the titer of which has been previously determined.
4. Complement—freshly pooled sera from three or more guinea pigs. Complement may prove to be one of the greatest sources of error in the test, thus making interpretations by the serologist difficult. Thomson, Park, and Hamann realized the instability of the complement and recommended the combined titration for both fixing and hemolytic powers. However, we found their procedure a somewhat laborious one. The hemolytic and fixability fractions can be assured by using the pooled sera of many guinea pigs, which when kept under optimum conditions of freezing or preservation and daily titration, will give good results.

In our laboratory pigs were bled once every week and the sera frozen in the refrigerator, 1 c.c. being placed in each of several test tubes. No complement after being thawed was returned for refreezing.

5. Patient's serum heated at 56° C. for fifteen minutes. Milky or hemolyzed sera are to be avoided.

As is recommended by Cohn, the inactivated serum is stored in the refrigerator overnight. Using freshly inactivated sera seems to give false serologic results due to increased lability of reactive substances.

Employing the use of sheep cells to remove native amboceptor is to be discouraged because of the number of anticomplementary reactions which are liable to occur. Too, large amounts of amboceptor are not easily removed by one absorption. The number of zone reactions which occur are so negligible that such technical complication is superfluous.

6. Gonococcus polyvalent antigen.

*Best polyvalent antigen available to us was donated by Parke, Davis & Co.
Received for publication, December 14, 1939.

Hemolytic titration: As bacterial antigens are rarely hemolytic, this titration may be completely omitted.

Anticomplementary titration: It is sufficient to titrate after the preparation of the antigen, and once every two months thereafter.

Antigenic titration: It is sufficient to perform this titration only once in every four to six weeks, using suitable positive control. In any case, the dose (2 units) employed in the test should be one-half to one-fourth the anticomplementary unit.

TABLE I

ANTIGEN TITRATION USING HEATED GONOCOCCUS-POSITIVE SERA

Antisera are not advisable as the antibodies vary so that the antigenic unit fluctuates according to the antiserum used. The antigenic unit is taken as the smallest amount of antigen giving complete inhibition of hemolysis. Two antigenic units are employed in the test.

ANTIGEN 0.5 C.C.	HEATED POSI- TIVE SERA 1:5 C.C.	COMPLEMENT 2 FULL UNITS C.C.	SENSITIZED SHEEP CELLS C.C.

Negative	0.2	0.3	0.5	1		1		
control								

Complement Fixation Test.—No evaluation of the degree of positiveness was attempted, but since the gonococcus antibody is produced in most cases in small amounts, we have employed 0.3 c.c. of serum in the first tube, a larger amount than usual.

The sensitized sheep cells were prepared by mixing equal quantities of 2 per cent cells with two units of amboceptor and 1 c.c. of the mixture is added

to each tube both in the test proper and the antigenic titration. The reactions have been clearer-cut and faster.

We found that icebox incubation for six to eight hours was superior to fifteen to eighteen hours as it decreases the number of anticomplementary reactions and nonspecific positives. This may be explained by the fact that there is less destruction or absorption of complement in a shorter incubation period.

Readings of the test are made when antigen, serum, and negative controls have all cleared. This usually takes from ten minutes to twenty minutes. In this way weakly positive tests are not overlooked.

HEMATOCRIT TUBE CLEANER*

ARTHUR C. STIRLING, M.D., ROCHESTER, N. Y.

THE cleaning and drying of fine bore hematocrit tubes of the Wintrobe type have been for some years a problem to the laboratory technician, intern, or medical student. Since the use of the hematocrit tube for blood sedimentation and erythrocyte volume determinations is constantly extending, especially in the study of arthritis and in following the progress of tuberculosis and other infections, there seemed to be merit in shortening at least one step in the process. The various methods employed to date have been time-consuming, bothersome and, if the blood is caked from long sitting, sometimes inadequate. The apparatus here described shortens the cleaning process to thirty seconds and eliminates the tediousness of other methods. The cleaner is conveniently used with equipment found in practically all hospital laboratories.

The cleaner consists of a chromium plated metal tube designed as illustrated in Fig. 1. The short arm is beveled and fits into the end of a rubber tube attached to a suction system; the same apparatus employed in cleaning the ordinary hemocytometer pipette may be used. The long arm, made of smaller bore stock, is long enough to extend nearly to the bottom of a Wintrobe hematocrit tube. In position for use this cleaner arm fits loosely inside the tube.

*From the University of Rochester School of Medicine and Dentistry.
 Received for publication, December 11, 1939.

Suction is applied at the beveled end which is connected to the rubber tubing. The hematocrit tube to be cleaned is slowly lowered over the long arm; the serum and packed blood cells are thus in great part removed. The cleaner with the hematocrit tube still in place is lowered into a wide-necked bottle containing water (Fig. 2). Water is sucked upward around the arm of the cleaner into the hematocrit tube and finally through the cleaner to the waste reservoir; the stream of water thus quickly removes clots of blood remaining in the tube. Agitation of the water, accomplished by repeatedly raising the tube above the surface of the water permitting bubbles of air to enter, increases the speed of the process.

Fig. 1.

Fig. 2.

Fig. 1.—Hematocrit tube cleaner showing beveled short arm for connection with suction system.

Fig. 2.—Hematocrit tube cleaner with Wintrobe tube in place showing method of use with cleaning fluids.

Following the use of water the cleaner and tube are lowered in a similar manner, first into a bottle of alcohol which removes the excess water, then into ether which removes the alcohol. Only small amounts of alcohol and ether are needed if ample water is used. When the hematocrit tube is slowly removed from the cleaner, it is thoroughly dried upon evaporation of the ether by the air sucked into it.

Grateful acknowledgment is expressed to Mr. Raymond J. Bott of the Will Corporation, Dr. John S. Lawrence, Dr. Doran J. Stephens, and numerous others who have aided substantially in the development of this instrument.

The style of cleaner shown in Fig. 1 is available from the Will Corporation, Rochester, N. Y.

CHEMICAL

A METHOD OF COLLECTING AND TRANSPORTING SMALL BLOOD SAMPLES FOR HEMOGLOBIN DETERMINATION*

MARY E. EWING, A.B., AND N. R. BLATHERWICK, PH.D.
NEW YORK, N. Y.

THE following procedure was evolved when it became desirable to determine the hemoglobin content of the blood of certain applicants for life insurance living at a distance from the laboratory. It allows the collection and transportation of small blood samples in a suitable condition for the determination of the hemoglobin content. The method is published in the belief that others may find it useful.

Blood is collected by capillary attraction from a finger-tip puncture into a roughly calibrated glass tube from which it is transferred into an accurately graduated pipette on being received in the laboratory. The tubes are lined with a small amount of hemolytic reagent and anticoagulant which are intimately mixed with the blood just after collection by tilting the tube and allowing the blood to flow from one end to the other. The tube is then sealed at both ends with plasticine and is sent to the laboratory in a kit designed for this purpose.

The kit consists of a cardboard carton containing two cellulose acetate tubes with metallic screw caps. One tube holds a spring lancet for making the finger-tip puncture, the other carries three capillary tubes, one of which is sealed with plasticine to show how this is done, the other two are prepared for the blood collection. Only one tube is needed but an extra one is included in case of mishap to the first. The plasticine is packed into a screw cap like those used to close the cellulose acetate tubes and is inserted in a glassine envelope for packing. To seal the blood tube after completing the collection, the ends are pressed through the plasticine against the metal cap several times until about $\frac{1}{4}$ inch of the bore is compactly filled. A bundle of slides, each in a glassine envelope, is bound with a rubber band and included in the outfit if an examination of the blood film is desired. Directions for taking the blood sample are printed on a folder which is wrapped around the two container tubes when packing them in the mailing carton. The outfit is sent as first class mail and requires only 12 cents postage. Similar kits are used for blood samples taken during sugar tolerance tests and for the Kline serologic test.

The capillary collection tubes are made from the smallest bore regular glass tubing available. The tubing has an outside diameter of 3 mm. and a bore of approximately 1.4 mm. It is cut into lengths of $5\frac{3}{4}$ inches, and the ends are

*From the Biochemical Laboratory of the Metropolitan Life Insurance Co., New York.
Received for publication, March 6, 1940.

smoothed down by rubbing on emery cloth or a similar abrasive. The tubes are marked with laboratory ink 4 inches from one end, the point to which blood is collected. On receipt in the laboratory the plugged ends of the tube are filed and broken off, and the blood is transferred from the tube to a 0.1 c.c. Folin capillary pipette by placing their tips together and allowing the blood to flow into the pipette.

Potassium oxalate is used as an anticoagulant and saponin to hemolyze the blood cells. The blood must be hemolyzed when it is freshly drawn, otherwise the cells are likely to settle along the bore of the tube or at one end and cannot afterwards be as thoroughly mixed with the plasma as this method requires.

Fig. 1.—Kit for obtaining and mailing small blood samples for hemoglobin determination and examination of blood films. One cellulose acetate tube containing the blood tubes and another holding the lancet are resting in the bottom of the mailer. The inner and outer covers of the mailer are shown. The cap containing the plasticine and the specimen tube sealed with plasticine are resting on the strip of paper. The blood tubes are shown at the left of the latter. The glass slides, glassine envelopes, a lancet, and a copy of the directions are also pictured.

Between the time of collecting and analyzing the blood, a measurable amount of methemoglobin forms at the expense of the oxyhemoglobin. The analysis is therefore, made according to Wu's cyanhemoglobin method¹ which determines both forms of hemoglobin. Oxyhemoglobin is first converted to methemoglobin by adding potassium ferri cyanide, and the methemoglobin is converted to cyanhemoglobin by the addition of potassium cyanide. The same procedure is applied to a standard blood solution which has been adjusted to an oxygen capacity of 4 volumes per cent by the manometric method of Sendroy.² A colorimetric comparison of the blood samples with the standard gives their oxygen capacity.

PREPARATION OF THE BLOOD TUBES

One-fourth gram of potassium oxalate ($K_2C_2O_4 + H_2O$) is dissolved in 2 c.c. of water in a 50 c.c. volumetric flask and 95 per cent ethanol is added until the oxalate is precipitated.

Eight-tenths gram of saponin is mixed with a little alcohol in a small beaker until smooth and rinsed with alcohol into the 50 c.c. flask containing the oxalate. The volume is made up to the mark with alcohol.

After thorough mixing, 2 or 3 c.c. of the alcoholic suspension are poured into a small beaker. The collecting tubes are filled to the mark to which blood is to be collected, and the particles are allowed to settle along the bore. Then a fold of an absorbent towel is applied to the tip of each tube in turn and the alcohol is drawn off as nearly as possible, leaving the oxalate and saponin in the tip of the tube. A slow current of air is then blown through the tip of the tube from a rubber tube, spreading the particles in a thin film in the bore of the tube.

DETERMINATION OF HEMOGLOBIN

A quantity of blood (15 or 20 c.c.) is standardized by the oxygen capacity method and diluted with 0.4 per cent ammonia solution to an oxygen capacity of 4 volumes per cent. This solution may be kept in an amber bottle in a refrigerator for a month or two without appreciable change.

One cubic centimeter of the standard blood solution is delivered into a 20 c.c. volumetric flask and diluted with 4 c.c. of 0.4 per cent ammonia solution.

Two cubic centimeters of 0.4 per cent ammonia solution are placed in a test tube accurately graduated at 10 c.c. One-tenth cubic centimeter of blood is delivered into the tube, and the pipette is rinsed several times with the ammonia solution.

One-fourth cubic centimeter of 0.4 per cent potassium ferricyanide solution is added to the blood sample and 0.5 c.c. to the standard. After twenty minutes 0.25 c.c. of 0.1 per cent potassium cyanide solution is added to the unknown and 0.5 c.c. to the standard. At the end of five minutes both solutions are diluted to the mark with water and the unknown is read against the standard in the colorimeter:

$$\frac{20 S}{U} = \text{Volumes per cent oxygen capacity.}$$

The cyanhemoglobin color is very stable, thus lending itself admirably to photoelectric and photometric determinations. We use the Leifo photometer made by E. Leitz, and for such readings the blood samples are diluted four times more than for colorimetric determination.

EXPERIMENTAL RESULTS

A series of 35 blood samples was kept at room temperature for periods varying from four to nine days, and the results were compared with the original values obtained on freshly drawn samples which contained neither oxalate nor saponin. The results are given in Table I. It will be seen that the figures for the preserved samples are in good agreement with those for the original samples. The values for the kept samples did not vary more than plus or minus 5 per cent

from the original values. During a period of five months we have received 108 blood samples collected by medical examiners in all parts of the country. These were entirely satisfactory for hemoglobin determination. Six samples were not collected satisfactorily. This is a good result when it is recalled that the procedure is a new one for the examiners.

TABLE I
OXYGEN CAPACITY OF FRESH AND PRESERVED BLOOD SAMPLES

SAMPLE	DAYS KEPT	OXYGEN CAPACITY IN VOLUMES PER CENT	
		FRESH SAMPLE	PRESERVED SAMPLE
1	6	20.0*	20.7*

34	8	19.2	19.5
35	8	20.9	21.3

*This value is an average of duplicate determinations.

SUMMARY

A simple and inexpensive procedure is given for obtaining small blood samples which are mailed to the laboratory from all parts of the country for hemoglobin determination. Similar procedures are also used for blood samples obtained during sugar tolerance tests and for the Kline serologic test.

A DISTILLING APPARATUS AND A PROCEDURE FOR THE DETERMINATION OF ALCOHOL IN BLOOD AND URINE*

GEORGE W. JOHNSTON, M.S., AND R. B. GIBSON, PH.D.
IOWA CITY, IOWA

THE apparatus permits the rapid distillation of the alcohol from blood or urine and its oxidation to acetic acid with dichromate and sulfuric acid under reflux. Thus the loss of alcohol and of the intermediate oxidation product, acetaldehyde, is avoided. Ground glass connections throughout and ease in cleaning reduce the chances of contamination with organic material to a minimum. The determination is simple. The specimen, mixed in picric acid solution, is distilled (Nieloux)¹ into dichromate solution, sulfuric acid is introduced through the reflux tube for the oxidation, and the excess dichromate is titrated in the receiving flask when cool with a ferrous sulfate-methyl orange mixture (Harger).² Duplicate analyses check usually within 1 per cent with a maximum error of not over 2 per cent.

The apparatus, of pyrex glass, is shown in Fig. 1. Duplicate distillation flasks and three or more receiving flasks are desirable. The total cost should not exceed \$50. A microburner is employed for heating. The apparatus is assembled with clamps and rings on an iron laboratory support stand. The set-up requires but little table space and may be left assembled for use.

ANALYTICAL PROCEDURE

Solutions.—1. Standard dichromate, exactly 2.1288 Gm. of potassium dichromate (analytical) are dissolved in and made up to 1,000 c.c. with distilled water.

2. A saturated solution of picric acid (recrystallized), approximately 12.5 Gm. to 1,000 c.c.

3. Titrating solution, a mixture of 60 c.c. of 50 per cent (by volume) sulfuric acid, 40 c.c. of 0.1 per cent methyl orange in N/40 sodium hydroxide, and 2 c.c. of ferrous sulfate solution (50 Gm. crystals and 30 c.c. of concentrated sulfuric made to 250 c.c.), the mixture to be prepared the day the analysis is done, and cooled to room temperature before using.

The Analysis.—The apparatus and other glassware used are to be chemically clean. Pipette exactly 10 c.c. of the dichromate solution into each of two receiving flasks and into two 250 c.c. Erlenmeyer flasks (to standardize the titration mixture). Introduce 20 c.c. of picric acid solution into each distilling flask along with a few chips of unglazed porcelain. Connect one receiving flask to the condenser. Pipette 1 c.c. of blood (after mixing the specimen) or of urine

*From the Pathological Chemistry Laboratory of the University Hospital, the State University of Iowa.

Received for publication, April 29, 1940.

distillation and oxidation for a duplicate determination. Next add 10 c.c. of water to each of the blank standard dichromate flasks and 20 c.c. of sulfuric acid, and cool to room temperature. The blanks and the unknowns in the receiving flasks are titrated with the red reducing titration mixture from a burette. The color change is from an orange or yellow-green through a clear green to a solution with a slight reddish tinge. The end point is sharp and most satisfactory.

Calculation.—Ten times the distillate titration is divided by the blank titration, and the result is subtracted from 10.00. The figure thus obtained, when multiplied by 50, gives the milligrams per 100 c.c. of the sample.

The apparatus and procedure described permit certain refinements for the determination of blood and urine alcohol content which should appeal to and will be recognized by the competent analyst. Regardless of the analytical procedure employed, results which are presented as evidence in court should be checked by analysis in duplicate, a customary requirement for reliable commercial testing and for research data. The analytical method outlined above will facilitate such checking.

Acknowledgment is made to Mr. Herman Wiegand of the Department of Chemistry for suggestions as to design and for the construction of this apparatus.

A RAPID SIMPLE TEST FOR SULFANILAMIDE AND ITS DERIVATIVES*

MILTON M. HARTMAN, M.D., SAN FRANCISCO, CALIF.

KNOWING the desirability of having an instantaneous simple test which employs only one common, cheap, and stable reagent for drugs of the sulfanilamide group, I wish to report my original application of an old and hitherto overlooked principle of organic chemistry. The reagent is one which most physicians probably already have in their offices. The test is applicable quantitatively to urine and qualitatively to other body fluids.

The tests heretofore, which are all either the original Marshall test or a modification of it, require the diazotization of the amino group on the benzene ring with nitrous acid and the coupling of the resulting compound in acid solution with dimethyl- α -naphthylamine (or a similar compound). An azo dye, usually red or purple, is thus formed and compared with a similarly treated standard solution in a colorimeter. This test, while very accurate and sensitive, requires four reagents, two or three intermediate filtrations, and for even a fast technician at least thirty minutes to perform all the steps and ob-

*From the Department of Medicine, Stanford University Medical School, San Francisco. Received for publication, August 2, 1940.

tain complete color development. All this, plus the necessity of having to make up the nitrite solution fresh each time, the expense and often nonavailability of the coupling reagent, and the inevitable high cost and delay in obtaining the desired information, result in such tests being applied much less frequently in ordinary clinical practice than they should be.

In my test the simple addition of para-dimethylaminobenzaldehyde (Ehrlich's reagent) in an acid solution to the tissue fluid produces an immediate bright yellow color. In this test the aldehyde group of the reagent reacts with the free amino group on the benzene ring of the sulfanilamide, sulfapyridine, or sulfathiazole, etc.

In the accompanying structural formula R may be any of numerous radicals in the para position. It may even be a hydrogen atom, for ordinary aniline gives a positive test. In order that the reaction may take place, it is necessary that the NH_2 (amino) group be unchanged; if even one of the H atoms is replaced by another radical, the reaction is blocked. Therefore it is a test for free (unchanged) sulfanilamide. In man these compounds are changed to a varying degree to the monoacetylated form. For example:

If the total (free plus acetylated) amount of these compounds is desired, it is necessary only to heat with hydrochloric acid; in the resulting hydrolysis the acetyl group is split off and the original compound is obtained. Similarly, acetanilid ($\text{CH}_3\text{CO.NH.C}_6\text{H}_5$) does not give the test, but when it is hydrolyzed by heat and acid with the production of aniline ($\text{C}_6\text{H}_5\text{NH}_2$), the test is obtained.

In order to understand the application of the test and its limitations, a brief study must be devoted to possible interfering substances and their elimination. (Most of these interfere with the Marshall test also.)

1. The reagent itself is yellow, and correction must, therefore, be made for it in a quantitative test.

2. Bilirubin (bile pigment) in serum or urine imparts a yellow color to it. Dilution of the urine to 1:200 usually eliminates this interference. If the amount of bilirubin is excessive, it may be precipitated out as insoluble calcium bilirubinate by the addition of calcium chloride solution.

3. Urobilinogen in urine yields a pink color upon addition of the reagent. Dilution of the urine to 1:200 does away with this interference in practically all cases. Shaking the urine with a few drops of hydrogen peroxide solution

to oxidize the urobilinogen to urobilin (which is nonreactive) is an additional precaution; this prevents the pink color formation even in concentrated urine.

4. Other urine pigments can be disposed of by diluting the urine so that there is no perceptible yellowness and then applying the test. The urine may be diluted freely, for the compounds are detectable in a dilution of 1:5,000,000.

5. Some drugs have a free amino group attached to a benzene ring. These would rarely be present without the knowledge of the physician, the drugs in question being procaine and the antisyphilitic arsenicals, arsphenamine, neoarsphenamine, mapharsen, etc.

6. Urea yields a faint yellow color when tested with the reagent, but since the test is about 500 times more sensitive to sulfanilamide than to urea, dilution of the urine or blood filtrate disposes of this interference.

7. Drugs with an acetyl-amino group attached to a benzene ring which yield a free amino-benzene group on acid hydrolysis would interfere in the determination of total sulfanilamide. The only two compounds in this class are acetanilid and acetphenetidin ($\text{C}_{11}\text{H}_{13}\text{NO}_2$). Neither of these compounds is ordinarily administered to a patient being treated with sulfanilamide or its derivatives, the bone marrow already being subjected to sufficient hazard.

8. Sodium nitrite yields a yellow color also, but the amounts administered would rarely if ever be quantitatively significant, and the color reaction is four times more sensitive with sulfanilamide and its related compounds.

9. Alkalinity causes interference because the reaction is obtained only in acid solution. The reagent and sulfanilamide yield no color in an alkaline solution, but the yellow color appears immediately upon acidification. The reagent is, therefore, prepared in concentrated hydrochloric acid as follows:

Para-dimethylaminobenzaldehyde	1.57 Gm.
Concentrated hydrochloric acid, C. P.	20.00 c.c.
Distilled water to make	100.00 c.c.

This formula is very similar to Ehrlich's reagent, which is already universally used as a test for urobilinogen in urine. The aldehyde is much more soluble in acid solution than in neutral solution. The exact proportions of reagent and acid were arrived at by experimentation to obtain the greatest color change in proportion to the color of the reagent itself. After the addition of the reagent the liquid to be tested should be definitely acid to litmus paper. If it is not, hydrochloric acid should be added until it is. This is particularly important with blood plasma and serum which are highly buffered at a pH of about 7.4. Protein precipitation may cause some interference and necessitate filtration. Excess acidification of any fluid is to be avoided because it reduces the color response after a certain point.

10. All other usual drugs, alkaloids, inorganic salts, glucosides, etc., do not interfere. The test was applied to all the remedies mentioned in *Useful Drugs*.

QUANTITATIVE DETERMINATION OF FREE SULFANILAMIDE, SULFAPYRIDINE, AND SULFATHIAZOLE IN URINE

This method employs the Klett-Summerson Photoelectric Colorimeter with its No. 42 (blue) color filter. The results obtained agree exactly with those

obtained by the diazotization methods (after the corrections which the latter require). All figures refer to readings on this instrument with distilled water at zero, and for those who do not possess such a colorimeter the figures obtained can be used as a basis to establish a set of color standards or as a basis upon which the usual colorimeter can be used. Directions are as follows:

1. Fill a Klett tube with distilled water and adjust colorimeter to give zero reading. Discard water.

2. Prepare a 1:200 dilution of the urine. To 10 c.c. of this solution in the Klett tube add one drop of hydrogen peroxide solution and invert several times.

3. Note reading R_n . This usually runs from one to five but may go up to ten.

4. Add exactly 0.2 c.c. of reagent and invert several times.

5. Note reading R_n .

6. Calculate by use of formulas to find concentration in the diluted urine.

Multiply by 200 to get concentration in original urine (undiluted).

$$\frac{R_n - R_n - 98}{7.5} = \text{Parts per million of sulfanilamide}$$

$$\frac{R_n - R_n - 98}{5.18} = \text{Parts per million of sulfapyridine}$$

$$\frac{R_n - R_n - 98}{5.06} = \text{Parts per million of sulfathiazole}$$

The figure 98 is obtained as follows: 0.2 c.c. of reagent in 10 c.c. of distilled water gives a reading of 96 with several brands of pure para-dimethylaminobenzaldehyde that the author has been able to obtain. (It might be well to check your own supply of this compound and adjust the concentration so that this figure is obtained, or to note the value that you obtain yourself.) In a 1:200 dilution of urine the urea present adds 2 to this figure, giving 98. By way of orientation it may be noted that 1:10,000 potassium dichromate (icterus index 1.0) gives a reading of 106.0. The test is most accurate with values in the diluted urine of 2 to 30 parts per million. If more is obtained, the use of a 1:400 dilution is advisable.

If a Klett colorimeter is not available, there are two other alternatives which give satisfactory results. The first is to match the color obtained with a set of permanent (stoppered) standards prepared from potassium dichromate. For example:

0.0094%	$K_2Cr_2O_7$	= 100.0 Klett	= Approx. zero p.p.m.
0.015%	$K_2Cr_2O_7$	= 159.0 Klett	= 7.9 p.p.m. Sulfanilamide
0.02%	$K_2Cr_2O_7$	= 212.0 Klett	= 15.0 p.p.m. Sulfanilamide
0.025%	$K_2Cr_2O_7$	= 265.0 Klett	= 22.0 p.p.m. Sulfanilamide
0.03%	$K_2Cr_2O_7$	= 318.0 Klett	= 29.0 p.p.m. Sulfanilamide

That is, R_n is obtained by comparison, and R_n is arbitrarily set at 2 in using the calculation formulas for the appropriate compound. The other alternative is to compare the color obtained in an ordinary colorimeter with 1:10,000 potassium dichromate, assigning to the latter the value of 106 and obtaining a value for R_n . A value of 2 can be assigned to R_n and the formulas applied.

QUANTITATIVE DETERMINATION OF TOTAL (FREE AND PARA-ACETYLATED) SULFANILAMIDE, SULFAPYRIDINE, AND SULFATHIAZOLE IN URINE

Heat 1 c.c. of urine and 1 c.c. of 2 normal hydrochloric acid in a covered beaker in a water bath (boiling) for thirty to sixty minutes. Let cool. Neutralize to litmus with 2 normal sodium hydroxide. Add water to make up to 200 c.c. Run determination as for free compound omitting the hydrogen peroxide, which is no longer necessary.

APPLICATION OF TEST TO OTHER BIOLOGIC FLUIDS (BLOOD, CEREBROSPINAL FLUID, GASTRIC CONTENTS, EXUDATES, ETC.)

The test is applicable qualitatively, but there are so many uncontrollable factors affecting the final yellowness that quantitative estimations are very unreliable. The more accurate diazotization method is to be preferred for quantitative work on such fluids. In using trichloroacetic acid filtrates of blood it is found that the color response is cut down below a usable level. In trying to use ethereal and alcoholic extracts of blood, we find that the varying color and turbidity plus the yellowness of the reagent cause insuperable difficulties.

NOTE: The solution of the reagent in acid decomposes only very slowly under ordinary conditions. This change can be further minimized by storing the solution in a cold, dark place when it is not in use.

A SIMPLIFIED UREA DETERMINATION FOR ROUTINE BLOOD CHEMISTRY*

HANS NORBERT NAUMANN, M.D., LOUISVILLE, KY.

THE determination of urea in blood can be simplified by placing urease, together with oxalate, in specimen bottles, so that the blood, still warm after withdrawal, is in contact immediately with urease. The urea, converted almost instantaneously, can then be determined by direct nesslerization in Folin-Wu filtrates which at the same time serve for the common routine determinations.

TECHNIQUE

One volume of sodium oxalate and two volumes of jack bean powder are mixed by shaking in a large brown bottle which serves as stock container.† For use, the powder mixture is filled into a salt cellar with a 5 mm. opening in the cap‡ and the desired powder quantity obtained by tapping the cap of the salt cellar against the neck of the specimen bottle. (Accurate measuring is not necessary as the blood to be placed into the bottle is, as a rule, not measured either. One milligram of oxalate per 1 c.c. of blood is sufficient; 20 mg. per 10 c.c. of

*From the Long Island College of Medicine Division, Kings County Hospital, Brooklyn. The present work was continued at the Jewish Hospital, Louisville.

Received for publication, August 31, 1939.

†This powder mixture, using jack bean meal of the Arlington Chemical Co., Yonkers, N. Y., has been kept at room temperature for six months at a time.

‡Suitable are glass salt cellars with screw caps of translucent plastic in which a hole can easily be bored.

blood offers a suitable excess. With a little experience, the volume of mixed powder to be taken is easily recognized.) Immediately after placing blood into the bottle, the latter must be rotated for thirty seconds to insure solution of the oxalate and even distribution of the urease. After five minutes at room temperature the specimen is ready for precipitation: Take 3 c.c. of blood and 24 c.c. of N/12 sulfuric acid, rotate, and set aside for a few minutes. Then add 3 c.c. of 10 per cent sodium tungstate, mix thoroughly, and filter through a 12.5 Whatman No. 1 (yield: about 20 c.c.). If the precipitation is red brown instead of black brown, usually caused by too much oxalate, add a drop of concentrated sulfuric acid. The reagents are best kept in 50 c.c. burettes connected with storage bottles.

For direct nesslerization 3 c.c. of Nessler's reagent and 2 drops of 10 per cent gum acacia are placed in a test tube. Five cubic centimeters of filtrate are blown into the reagent and compared with 5 c.c. of a standard containing 0.00707 per cent of ammonium sulfate (equal to 1.5 mg. per cent N and 0.5 per cent Na_2SO_4). Holding the tip of the pipette at the edge of the test tube, blowing as forcefully as possible, and directing the jet of filtrate directly into the Nessler reagent (prepared according to Boek-Benedict) gives the clearest solutions. Gum acacia (10 per cent in 0.25 per cent benzoic acid) is added to keep the solution stable for at least thirty minutes. The addition of sodium sulfate to the standard gives the same electrolyte concentration as in the filtrate, with an identical color tinge and an identical faint haziness after standing. If necessary the 8 c.c. of unknown solution are diluted with distilled water.

TABLE I

COMPARATIVE ANALYSIS OF BLOOD SAMPLES WITH AND WITHOUT ADDITION OF JACK BEAN POWDER AFTER STANDING 3 TO 5 HOURS AT ROOM TEMPERATURE

ANALYZED FOR	METHOD	NO. OF SAMPLES ANALYZED	MEAN OF RESULTS IN MG. % JACK BEAN POWDER		MEAN OF DIFFERENCES %
			NOT ADDED	ADDED	
Glucose	Folin-Wu	125	118	125	7.1
Creatinine	Folin	52	1.91	1.90	5.5
Uric acid	Benedict	26	3.33	3.11	7.7
Chlorides	Whitehorn	21	469	469	3.2
Nonprotein nitrogen	Folin-Myers	20	36.9	41.7	30.0

Interference.—Before using the described technique generally for routine chemistry, it was necessary to investigate whether or not the addition of jack bean powder to oxalated blood interferes with the common routine tests. It will be seen from Table I that with the exception of nonprotein nitrogen determinations, the mean results obtained in samples without addition of jack bean agree within the limit of methodical error with those obtained in samples with addition of jack bean. Nonprotein nitrogen values in samples containing jack bean powder are too high and cannot be used. However, the addition of jack bean powder to oxalated blood does not interfere with the determination of glucose, creatinine, uric acid, and chlorides in the Folin-Wu filtrate.

Glycolysis.—To prevent glycolysis it is possible to use, instead of oxalate, sodium fluoride, which, on the other hand, retards the urease action. In the presence of sodium fluoride and high urea concentrations the enzymatic reaction

takes about one hour at room temperature and about half an hour in the incubator (see Table II), while in normal blood the reaction is completed in about thirty and fifteen minutes, respectively. High values obtained after twenty-four hours are due to the fact that ammonia is split off from protein as observed also by Sander.

For longer preservation of blood samples, for sugar tolerance tests, in cases of diabetes, etc., the use of sodium fluoride is necessary. If urea is to be determined in specimens containing sodium fluoride, completion of the hydrolysis of urea must be insured by allowing sufficient time for the reaction. For general routine work, however, oxalate is preferable, provided that the error due to glycolysis is minimized by precipitating the blood either after five minutes or after a certain constant time, and allowing for the decrease of glucose concentration.

TABLE II

GLYCOLYSIS AND UREASE ACTION IN OXALATED AND SODIUM FLUORIDE SAMPLES OF THE SAME BLOOD

TIME	OXALATED BLOOD AND JACK BEAN AT 20°		NAP BLOOD AND JACK BEAN AT 20° AT 38°

COMMENT

The method of adding urease to oxalated blood, incubation, and subsequent direct nesslerization of the Folin-Wu filtrate was devised by Myers in 1921. This principle was adopted also by Van Slyke and Plazin, but without incubation, and substituting Somogyi's zinc* for Folin-Wu's tungstic filtration.

The technique of placing oxalate-urease powder directly in specimen bottles, as described, was used in our department during the past year and proved advantageous for the following reasons: (1) Time and labor saving. (2) Eliminates incubation, urease extracts, and buffer. (3) Rapid action of urease. (4) Clear solutions. (5) No interference with routine determinations of glucose, creatinine, uric acid, and chloride.

SUMMARY

A routine urea determination in blood has been described with the technical feature of placing an oxalate-jack bean powder mixture in specimen bottles effecting rapid hydrolysis of urea in the still body-warm blood. The urea is determined by direct nesslerization in the Folin-Wu filtrate which can be used also for other routine tests.

I am indebted to Dr. Hamilton J. Crawford, Director of the Department of Medicine at the Long Island College Division, Kings County Hospital, Brooklyn, and Dr. Carl H. Greene, Clinical Professor of Medicine, for their help and interest in the present work. I wish to thank also Miss Sylvia Held, M.A., for doing part of the analyses.

*Somogyi's copper filtrate likewise gives true sugar values and contains less substances interfering with Nessler's reaction. It is free of uric acid.

MODIFIED TECHNIQUE FOR PROTHROMBIN DETERMINATION IN BLOOD*

H. S. HOLMBOE, M.D., AND R. W. HOLMBOE, B.A., SANTA BARBARA, CALIF.

THE tests for prothrombin content of blood in general use are those of Quick, Brinkhous, and Smith. The determination of prothrombin by the technique of Brinkhous and Smith involves many reagents and is difficult to perform. Quick, however, has evolved a method which is simple, accurate, and inexpensive, but there are several objections to his technique; namely, the reagents must be made up fresh for each determination, the concentration of thromboplastin is variable, and the normal time value for the method is too short. This favors error in reading and does not permit the measurement of prothrombin levels above normal.

It was felt that these objections to Quick's method were valid and that a modified test might be evolved which would overcome them. Early in our experimental work we investigated several sources of thromboplastin, namely, dried brain tissue from the rat, guinea pig, rabbit, sheep, and man. The variation in results obtained with these sources of thromboplastin is shown in Table I. All tests were performed according to the technique of Quick.¹²

Subsequently the effect of varying the concentration of thromboplastin, plasma, and calcium chloride in different combinations was determined. These findings, as shown in Table II, may be summarized as follows: (1)

*From the Department of Pathology, Santa Barbara Cottage Hospital.
Received for publication, November 27, 1939.

Increasing the proportion of plasma decreases the prothrombin time. (2) Increasing the proportion of thromboplastin decreases the prothrombin time except in the case of thromboplastin from the rat. (3) There is an optimum concentration of calcium chloride for each type of thromboplastin. Increasing or decreasing this concentration prolongs the prothrombin time. (4) There is an optimal concentration of all reagents for each type of thromboplastin.

TABLE I

AVERAGE VALUES ARE GIVEN WITH STANDARD DEVIATIONS FOR EIGHT BLOOD SAMPLES

THROMBOPLASTIN FROM	PROTHROMBIN TIME (SECONDS)
Rat brain	87 ± 2.8
Guinea pig brain	201 ± 10.3
Rabbit brain	32 ± 0.9
Sheep brain	118 ± 6.2
Human brain	72 ± 1.8

The tests were made with optimum concentration of reagents (see Table II).

After a series of preliminary experiments and primarily because of its stability, an ether-soluble, acetone-insoluble extract of sheep brain was chosen as a thromboplastic agent for use in a modified technique. Its preparation is described subsequently.

MODIFIED TECHNIQUE

1. Plasma from oxalated blood is used. A mixture of 4.5 c.c. of blood and 0.5 c.c. of sodium oxalate gives sufficient plasma for several determinations. To separate the plasma from the cells, the blood is centrifuged for fifteen to twenty minutes at high speed to throw down as much of the tissue debris and as many cellular elements as possible.

2. Into a small glass tube (serology tubes 3 by $\frac{9}{16}$ inches and 4 by $\frac{1}{2}$ inches are adequate) 0.2 c.c. of plasma is accurately pipetted with a Kahn pipette. To this is added 0.2 c.c. of the thromboplastin solution. (Stock solution is diluted with normal saline 1:5 on day of test.)

3. The mixture is incubated at 37° C. in the water bath for seven minutes.

4. The tube is then removed from the water bath, the outside of the tube is dried, and exactly 0.2 c.c. of calcium chloride is *immediately* added.

5. The tube is then shaken to insure adequate mixing. It is slanted and rotated at fifteen-second intervals. The interval between the addition of the calcium chloride and clot formation is measured with a stop watch. This constitutes the prothrombin time.

REAGENTS

1. *Sodium Oxalate*: 1.34 Gm. of C. P. anhydrous sodium oxalate are dissolved in 100 c.c. of distilled water. This solution is tenth-molar and is nearly isotonic.

2. *Thromboplastin Stock Solution* (ether-soluble, acetone-insoluble brain extract): A fresh sheep brain is washed in water. The meninges and blood vessels are carefully removed. The brain tissue is then cut into pieces as small as possible and is dried with acetone. Repeated additions of acetone and grinding in a mortar facilitate this process. The final product is freed of acetone by centrifuging, carefully decanting the acetone, and drying the powder in the

†Note effect of doubling thromboplastin. (Compare lines 1 and 4.)

‡Note effect of doubling calcium chloride. (Compare lines 1 and 6.)

§Note optimum concentration of calcium chloride. This optimum is only apparent with rat, guinea pig, and sheep thromboplastin. With rat, rabbit, and human thromboplastin note the range in which the concentration of calcium chloride has but slight effect (indicated by brackets).

open air. The dry powder is then completely extracted with repeated small portions of ether until no precipitate is obtained by addition of acetone. To the combined portions of the ethereal extract, acetone is added until no more of the extracted material can be precipitated from the solution. The precipitated substance is separated from the ether-acetone mixture by centrifugation. It is then air-dried and kept in a stoppered vial in the icebox. The finished product is a light brown, waxy substance which darkens on standing. A normal yield from an average sheep brain is about 5 to 10 Gm. In the preparation of the stock solution 0.25 Gm. of the substance is emulsified in 50 c.c. of normal saline, and aqueous merthiolate is added as a preservative to a concentration of 1:100,000. The saline suspension is warmed to 56° C. for ten minutes to facilitate mixing, and during this time it is thoroughly shaken. The finished product is a homogeneous opalescent mixture which for test purposes is diluted 1:5 with normal saline. We have kept the stock preparation in the refrigerator for as long as three to five months without the slightest evidence of deterioration. Brief experiments with a similar extract from rabbit brain revealed that it gave practically the same values for prothrombin time as did thromboplastin from the sheep brain.

3. *Calcium Chloride*: 1.11 Gm. of C. P. anhydrous calcium chloride is dissolved in 800 c.c. of distilled water, giving a final concentration of eightieth-molar.

All reagents except the thromboplastin are stored at room temperature.

DISCUSSION

The essential factors involved in such a test are multiple, each in turn having its separate influence upon the clotting phenomenon. Any test concerning the clotting mechanism must attempt to keep the variability of these factors at a minimum. The following techniques have been found most important and difficult to standardize:

The proportion of oxalate to whole blood is very important, and the ratio of 1:10 should be strictly adhered to. Experimentally, doubling the quantity of oxalate will increase the prothrombin time 200 per cent. Varying differences in prothrombin times may be obtained by concentrations between these extremes. Slight hemolysis in the sample of blood does not alter the prothrombin time appreciably, but gross hemolysis does shorten it sufficiently to invalidate the determination.

Although it is desirable to determine the prothrombin time of a sample as soon as possible, oxalated whole blood will usually keep satisfactorily in the icebox for twenty-four hours without material alteration in the level of prothrombin if the plasma is not separated from the cells. Individual samples of blood have been kept as long as seventy-two hours, with an alteration in prothrombin content of only about 15 per cent. Recent work in connection with blood stored in "blood banks" indicates that most blood shows a marked deterioration of prothrombin within twenty-four hours and that it is almost depleted in forty-eight to seventy-two hours. The rate of destruction or fixation is probably an individual characteristic and cannot be predetermined.

It is important that the concentration of all reagents, and particularly neutral salts, be maintained at a uniform level. Normal saline must be used

in the thromboplastic solution because an excess of sodium chloride will materially delay the clot formation. This phenomenon is not universal, and individual samples of blood vary in their susceptibility to this change.

TABLE III
TEST AS OUTLINED, USED IN ALL CASES

INCUBATION PERIOD (MINUTES)	PROTHROMBIN TIME (SECONDS)						SPREAD	AVERAGE
	CASE							
	1	2	3	4	5	6		
0	101	153	176	222	290	202	121	173.6
2	66	78	82	86	80	85	20	79.5
4	65	82	88	95	93	89	30	83.3
6	65	71	77	80	79	83	18	74.3
7*	61	67	74	72	69	70	13*	65.8*
8	58	79	87	92	84	86	34	82.6
10	65	88	99	102	87	96	37	89.5
12	68	93	104	108	94	98	40	94.2

*Note minimum spread and shortest prothrombin time.

In the reading of the test the end point is taken as the time when the mixture first begins to show a fibrin web after gentle periodic rotation. Many times this point is coincidental with complete clot formation. Again it may precede complete clotting by ten to twenty seconds. Violent agitation of the tube after addition of the calcium chloride will delay the clot formation.

During the formation of a clot it has been determined that the pH of the solution is only slightly altered toward the alkaline side. Samples of serum before, during, and after clot formation do not vary appreciably in their pH range. Consequently in most instances it is not necessary to regulate this factor since the normal buffer systems existing in the blood plasma are sufficient to keep the pH within normal limits under conditions of the test.

TABLE IV

TIME GROUP (SECONDS)	CASES	PER CENT
55-60	15	5.8
60-65	45	18.1
65-70	59	23.9
70-75	67	26.8
75-80	58	23.2
80-85	6	2.2
Total	250	100.0

The incubation period is the time interval during which the mixture of thromboplastin and plasma stands before the addition of the calcium chloride. Table III shows the alteration in prothrombin times with varying periods of incubation. The period of incubation which gave the shortest prothrombin time and the most constant results was found to be seven minutes. The decrease in prothrombin time to an optimum at seven minutes' incubation is probably due to the maximum release and formation of thrombin from the plasma. It is probably necessary for a given concentration of thrombin to be formed before it can act as an enzyme in the clotting mechanism. Although it is well known that, given sufficient time, a very small amount of thrombin can convert large quantities of fibrinogen to fibrin, there is apparently an optimum concentration at which it acts. The spread of individual determinations is probably due to the separate rates of release of thrombin or its precursor, prothrombin. Why there is an increase in prothrombin time with longer than seven minutes'

incubation is not easily understood, since thrombin and prothrombin are believed to be very stable. Some light may be thrown on this question by the work of Mertz, Seegers, and Smith,²⁶ who have suggested that an antiprothrombin is formed which may be thrombin itself.

In all tests involving colloidal chemistry unexplained variations commonly occur. If this fact is not recognized, considerable error may creep into their interpretation. For this reason, it is advisable to evaluate a normal control with each sample of supposed pathologic blood. It is also advisable, unless there is other clinical evidence of a prothrombin alteration, that all abnormal values be checked with repeated specimens of blood before therapy is instituted.

CLINICAL EVALUATION

For purposes of clinical evaluation of this test samples of blood from 250 consecutive patients admitted to the Cottage Hospital were tested. None of these patients had clinical evidence of alteration in their blood prothrombin level. The spread of the entire 250 determinations was from a minimum of 55 seconds to a maximum of 85 seconds. Table IV indicates that the range of normal values for this test lies between 60 and 80 seconds, with an average of 70 seconds since 92 per cent of the cases fall in this bracket. The determinations of the prothrombin time can be converted to per cent of prothrombin by considering the normal or 100 per cent to have a prothrombin time of 70 seconds.

We also used this test as a diagnostic procedure on two patients who were suspected of having lowered prothrombin levels of their blood. An omentopexy was performed on one patient with advanced cirrhosis. During his convalescence this patient developed bleeding from his gums and gastrointestinal tract. Prothrombin determinations were made, and an initial value of 187 seconds was found. Therapy with vitamin K reduced this to 95 to 100 seconds, with a marked cessation in bleeding within a period of twenty-four hours. A second patient had marked jaundice of an obstructive nature and an elevated prothrombin time of nearly 200 seconds. Subsequent treatment with vitamin K reduced this to 85 seconds in the course of three days.

SUMMARY

Due to the objections to the present tests in use for the determination of prothrombin in blood, a modified technique has been evolved which overcomes these defects and in addition has the essential factors of adaptability, simplicity, accuracy, and economy. A new thromboplastic agent which is stable and easily prepared has been made from sheep brain. The modified technique has been adequately tested clinically and has been found to be satisfactory.

AN INEXPENSIVE ALTERNATING CURRENT PHOTOELECTRIC COLORIMETER*

RUSSELL H. MORGAN, M.D.,† AND SIDNEY WEINHOUSE, Ph.D.‡
CHICAGO, ILL.

A RECENT communication¹ described an inexpensive direct-reading photoelectric colorimeter suitable for clinical use and designed to operate from small, portable dry batteries. In some circumstances the use of an instrument operated from alternating current may be more convenient. Alternating current colorimeters that regulate their light source potential by means of so-called constant-voltage transformers, however, have not been entirely satisfactory. Their erratic performance can be traced to line-voltage variations, not completely minimized by the regulating devices that were available. Recently transformers with adequate control have been developed, making possible the modification of our battery colorimeter for use with alternating current without loss of stability or precision. The new model (Fig. 1) can be constructed easily by anyone familiar with electrical apparatus from parts obtainable at a very low cost from any radio or electric supply house.

DESIGN

The colorimeter shown schematically in Fig. 2 operates as a direct-reading instrument. A solution whose concentration is to be determined is subjected to the usual chemical procedure prerequisite to a colorimetric examination. A sample of the resultant preparation is placed in a test tube, and light from a small incandescent lamp is projected through it. The transmitted light, after passing through a selective color filter, falls on the sensitive surface of a photoelectric cell; in response to the radiation a small electric current is generated. The current is amplified many times by a vacuum tube amplifier and is recorded by a milliammeter. This reading is transposed into terms of solution concentration by a graph prepared after calibrating the instrument with samples of known concentration.

The light source, *L. S.*, is a lens-end type, No. 222 Mazda flashlight bulb. This lamp by its unique construction provides abundant light at relatively low filament temperatures, thereby assuring long filament life and freedom from undesirable heating effects.

The selective color filters are of the Wratten gelatin variety and are obtainable from the Eastman Kodak Co. We have found four types to suffice for all colorimetric examinations usually encountered in the clinical laboratory. These are the blue, No. 47, used in blood sugar determinations; the green, No. 55,

*From the Henry Baird Favill Laboratory of St. Luke's Hospital, Chicago.

used in hemoglobin, nonprotein nitrogen, urea nitrogen, uric acid, and creatinine determinations; the yellow, No. 8, used in calcium and phosphorus determinations; and the red, No. 25, used in cholesterol determinations. The choice of the proper filter for other determinations will be discussed later.

The photoelectric cell, Ph , is a rubidium-coated R. C. A. type 926 phototube. Its spectral characteristics make it especially suitable for colorimetry. Although its current response to incident light is extremely small, expensive galvanometers or microammeters are not needed in its circuits because of the tube's adaptability to current amplifier circuits.

Fig. 1.—The colorimeter. The control on the left changes selective color filters; that on the right operates the power switch and regulates light source intensity.

The amplifier is a single stage, twin triode type. The two triodes of an R. C. A. type 6F8-G radiotron, V_1 , are arranged in a balanced Wheatstone bridge circuit in which plate resistances occupy two of the arms; R_4 , a 100-ohm potentiometer, and R_b and R_L , 1,000-ohm, 0.5-watt resistors, occupy the remaining two. The balance of the bridge is controlled by R_4 . The phototube current flows through R_c , a 20-megohm, 0.5-watt resistor; the potential developed across it is applied directly to the grid of one of the triodes. To maintain the amplifier in a state of balance at all times, R_g , another 20-megohm, 0.5-watt resistor, is connected between the grid of the other triode and ground. Proper grid potentials are obtained by R_a , a 200-ohm, 0.5-watt resistor. A 0.1 milliammeter, $M. A.$, connected across the amplifier bridge, measures the amplified phototube current. A 0.02-microfarad condenser, C_s , inserted across R_c , slows the action of the milliammeter.

The great stability of a twin triode amplifier makes it preferable to other types. Several were set up in the laboratory and operated continuously for 500 hours. All remained balanced during this time, even though line-voltage fluctuations often were as great as 10 per cent. When the power to an amplifier

C_1 and C_2 , filter condenser block; CF , selective color filter assembly; Ch , filter choke; PS , phototube shield; R_4 , amplifier balancing potentiometer; T_2 , 6.3 volt transformer; TTR , test tube receptacle; V_1 , amplifier tube socket, V_2 , rectifier tube socket.

Fig. 4.—A, optical system; a, circular glass plates with interposed selective color filters; b, filter control shaft; c, front panel; d, shaft bearing; e, projection chamber containing flash-light lamp; f, phototube and socket; g, phototube shield; h, subpanel; j, test tube receptacle B, arrangement of selective color filters between circular glass plates.

ometer, R_2 , are mounted on the front panel; the remaining parts are placed inside the cabinet on a subpanel and arranged as in Fig. 3.

The structural details of the optical system are shown in Fig. 4A. An aluminum block, 4 by 2 by 1 inches, drilled according to the specifications outlined, forms a projection chamber for the flashlight lamp and a receptacle in which test tubes containing solutions to be examined can be inserted. The flashlight lamp is mounted in a miniature screw base socket firmly bolted to the block. Light passes from the projection chamber to the test tube receptacle through an opening $\frac{3}{16}$ inch in diameter; another opening, $\frac{3}{8}$ inch in diameter, on the opposite side of the receptacle, conducts transmitted light to the phototube, mounted directly in front of it within a metal shield, $3\frac{1}{2}$ by $1\frac{3}{8}$ by $1\frac{3}{8}$ inches, to exclude stray light.

The four selective color filters are mounted between two circular glass plates, 2 inches in diameter and $\frac{1}{16}$ inch in thickness, having holes $\frac{5}{32}$ inch in diameter drilled through the centers and sealed at the edges with Duco cement (Fig. 4B). This filter assembly is placed between the aluminum block and phototube shield and is bolted to a brass shaft, 3 inches long and $\frac{1}{4}$ inch in diameter, supported by a bearing attached to the front panel of the colorimeter. By rotating the shaft the operator can quickly move any of the four filters into the path of the light beam.

OPERATION

Balancing the Bridge.—When the colorimeter has been assembled, the first procedure is to balance the amplifier bridge. The flashlight lamp is removed from its socket, the line cord plugged into an alternating current outlet, and the potentiometer, R_2 , rotated to the right. In the first few degrees of rotation, the switch, Sw , is closed and the power turned on. Before any adjustments are made, the colorimeter should operate continuously for twenty-four hours. Since new amplifier tubes require several hours of heating to become stabilized, efforts to balance the bridge permanently before stability is attained are wasted. When the prescribed time has elapsed, the potentiometer, R_2 , mounted on the subpanel of the instrument, is rotated until the milliammeter needle is brought accurately to its zero scale position. The amplifier circuit is then balanced and needs to be readjusted only if an amplifier tube is changed. When the flashlight lamp is replaced in its socket, the colorimeter is ready for operation.

Matching the Absorption Tubes.—Ordinary soft glass test tubes, 5 or 6 inches long and $\frac{5}{8}$ inch in outside diameter, are used as absorption cells. To obtain a set of tubes of identical light transmission, it is suggested that several dozen be purchased, cleaned carefully with sulfuric acid-dichromate cleaning mixture, and filled with distilled water. A sample tube is placed in the instrument, the power turned on, and the potentiometer, R_2 , rotated until the milliammeter needle is brought to any convenient position near full scale. The meter deflection produced by each of the tubes is noted, and those whose readings deviate more than 0.5 of 1 per cent from the mean are discarded. The remaining ones are kept for colorimetric use.

Choosing a Selective Color Filter.—Photoelectric colorimeters measure the percentage light absorption of solutions submitted for examination. The re-

lationship between light absorption and solution concentration can be expressed, according to the Beer-Lambert law, by the equation,

$$\log \text{ per cent absorption} = KCX,$$

where C is the concentration of the solution examined, X is the length of the solution through which light passes, and K is a constant. For a particular set of matched absorption tubes, X is a constant; therefore, the concentration is proportional to the logarithm of the light absorbed or inversely proportional to the logarithm of the light transmitted. The value of K depends upon the wave length of the light transmitted by the solution. In some portions of the spectrum the absorption is relatively small; in regions corresponding to the positions of the solution's characteristic absorption bands it is much greater. When various selective color filters that transmit light only in limited regions of the spectrum are used, the absorption can be made to have a wide range of values. It obviously is desirable not to have the absorption too small, for then it becomes difficult to measure. On the other hand, it is evident by differentiating the equation that, when the absorption becomes too great, large changes in concentration produce very small changes in light absorption, equally difficult to estimate. Satisfactory performance is attained if the absorption is restricted to less than 70 per cent of the incident light. Generally, a filter of the color complementary to that of the solution examined fulfills these conditions. In some instances, however, as for example in the Folin-Wu determination of blood sugar, the color density of the solution is so great that a filter having a color similar to that of the solution should be used. Regulation can be achieved in other ways, namely, by altering the amount of substance taken for analysis or by changing the volume of the final dilution.

When the proper filter is to be selected, a solution is prepared having the maximum concentration desired to be determined. With a test tube of distilled water in the receptacle, the meter is set at full scale deflection by the potentiometer, R_2 . Then the distilled water is replaced by the colored solution, and the readings are noted with each of the four filters. That solution which produces a deflection not exceeding about 70 per cent of the full scale is chosen for the particular determination.

Making a Determination.—A series of standard solutions having concentrations ranging from the lowest to the highest values expected to be encountered in the laboratory is prepared. A solution having zero concentration is also included. With the proper filter in place and a tube of distilled water in the receptacle, the meter is set at full scale deflection. The distilled water is then replaced in turn by each of the standard solutions and the meter reading of each recorded.

Calibration of the instrument can be carried out in several different ways. One method is to determine the specific extinction coefficient, $E_{sp.}$, in the equation,

$$E_{sp.} = \frac{\log \frac{T_0}{T}}{C},$$

where T_0 is the meter reading of the solution having zero concentration, T is the meter reading of one of the standard solutions, and C is its concentration. The mean of the various values of the coefficient can then be used to calculate the concentration of any solution according to the formula,

$$C = \frac{\log \frac{T_0}{T}}{E_{sp.}}$$

A more direct method of calibrating the colorimeter is simply to make a graph plotting solution concentrations against the logarithms of the meter readings. A line is drawn through the points, and concentrations can be read directly from the graph. An improvement of this method is to plot the graph on semilogarithmic paper, with meter readings placed along the logarithmic axis. Observations then can be converted directly to concentration values without calculation. Once the calibration curve is made, it is unnecessary to prepare standard solutions in making subsequent determinations, except as an occasional check or when new reagents are prepared. When a determination is made, the power to the instrument is simply turned on; two minutes are allowed for the amplifier and flashlight lamp to heat; the proper selective color filter is inserted; the potentiometer, R_2 , is adjusted for a full scale deflection of the meter with a test tube of distilled water in its receptacle; and the reading of the specimen is observed. The concentration is evaluated from the calibration curve.

If a series of consecutive determinations is to be made, it is advisable from time to time to check the position of R_2 . Fatigue of the light source causes a slow drift of the meter needle, making slight readjustments necessary. When the colorimeter has been in operation for ten minutes, the rate of drift is 0.25 of 1 per cent per minute.

In addition to the general principles of operation outlined, no attempt will be made to discuss the application of the instrument to specific problems. Many recently published reports describe the use of direct-reading photoelectric colorimeters in a great many clinical laboratory procedures.

SUMMARY

An inexpensive photoelectric colorimeter suitable for clinical use and designed to operate from alternating current outlets is described. Complete details of design, construction, and operation are included. Performance comparing favorably with that of commercial colorimeters can be expected. Operation is extremely simple.

THE PHOTELOMETRIC DETERMINATION OF BILIRUBIN IN URINE WITH DIAZOBENZENESULFONIC ACID*

WILLIAM H. GOODSON, JR., M.D., AND CHARLES SHEARD, PH.D.
ROCHESTER, MINN.

A SIMPLE, rapid and accurate procedure for the quantitative estimation of urinary bilirubin has been developed for use with the Sheard-Sanford photometer. This instrument makes use of spectral filters selected to transmit light chiefly in the region of maximal absorption of the substance under test, and thereby deletes the effects of extraneous colored substances or other regions of spectral absorption which may be present in the solution. The photometer also eliminates personal error in color matching and dispenses with the need for artificial standards.

The photometer is calibrated for bilirubin in the manner described by Osterberg, except that it is not necessary to evaporate the solution of bilirubin in chloroform to dryness. A weighed sample of bilirubin is dissolved in chloroform, and serial dilutions corresponding to convenient concentrations of bilirubin are prepared. Two milliliter portions of these solutions, to each of which is added a small quantity of alcohol, are treated with 1 ml. of the diazo reagent and are made up with alcohol to a final volume of 10 ml. These solutions are compared with water in the photometer.

For the calibration in terms of bilirubin, a spectral filter that has its maximal transmission in the region of 530 to 550 $m\mu$ is chosen. It is most satisfactory to construct the calibration curve on semilogarithmic paper; this makes it easy to select any desired scale value (such as 50) as the reading which corresponds to a solution free of bilirubin. Less than full scale deflection may be desired when small amounts of solution are to be examined; for, if light passes above the meniscus of the solution, the accuracy of the readings is lost.

METHOD

A method for the determination of urinary bilirubin is herein proposed.

Solutions.—1. *Caffeine sodio-benzoate and buffer solution.* Mix equal parts of a 25 per cent solution of caffeine sodio-benzoate† in distilled water and Sørensen's phosphate buffer pH 6.6. The buffer is most conveniently prepared‡ by mixing 60 ml. of one-fifth molar potassium dihydrogen phosphate (13.617 Gm. of KH_2PO_4 in 500 ml. of water), 40 ml. of one-fifth molar dibasic sodium phosphate (17.814 Gm. of $Na_2HPO_4 \cdot 2H_2O$ in 500 ml. of water), and 200 ml. of water.

*From the Mayo Clinic, Rochester.

†Received for publication, March 25, 1940.

‡Caffeine sodio-benzoate (U. S. P. X) is defined as "a mixture of caffeine and sodium benzoate which contains, when dried to a constant weight at 80° C., not less than 47 per cent nor more than 50 per cent of anhydrous caffeine ($C_8H_{10}O_2N_4$), and not less than 50 per cent nor more than 53 per cent of sodium benzoate ($NaC_6H_5O_2$)"

§Modified from the description of Clark.

2. *Acid blank solution.* Dilute 7.5 ml. of concentrated hydrochloric acid with water to make one liter.

3. *Diazo reagent.* Note that although this diazo reagent contains the same substances as Ehrlich's diazo reagent and many of its modifications (such as the so-called van den Bergh reagent), the concentrations are less in the one described here.

I. Sulfanilic acid ($\text{C}_6\text{H}_4(\text{NH}_2)(\text{SO}_3\text{H}) + 2\text{H}_2\text{O}$) 1 Gm., concentrated hydrochloric acid 15 ml., and water to make one liter.

II. Sodium nitrite (NaNO_2) 0.5 Gm. and water to make 100 ml. For use, take 0.3 ml. of solution II to 10 ml. of solution I, and dilute with water to make 20 ml.

PROCEDURE

To each of two tubes, "blank" and "test," add 2 ml. of fresh centrifuged urine and 2 ml. of caffeine sodio-benzoate and buffer solution (1). Mix well by rotating the tubes, and let stand for ten minutes or a little longer. To tube "blank" add 1 ml. of acid blank solution (2) and 5 ml. of water. To tube "test" add 1 ml. of diazo reagent (3) and 5 ml. of water.

Let both tubes stand for ten to fifteen minutes. With the same filter which was used in calibrating the photometer in place and the contents of the "blank" tube in the test cell, adjust the instrument to the scale value which corresponds to a solution free of bilirubin, and then substitute the contents of tube "test" in another cell. From the scale reading and the calibration curve, determine the content of bilirubin. If the content of bilirubin in the urine is too high to be read within the range of the instrument, the urine may be diluted with water, and the test repeated.

SPECTROPHOTOMETRIC AND PHOTELOMETRIC EXPERIMENTS

With methods hitherto employed for the quantitative determination of urinary bilirubin, it has been necessary to resort to adsorption of the bilirubin to an inert precipitate (Hunter,⁵ Naumann, Jendrassik, and Grof) in order to avoid interference from other urinary substances. In the case of the procedure which we have described, this same result is achieved through control of the pH of the reaction mixture and use of the urine (a colored solution), properly diluted, as a "blank" for adjusting the photometer before taking a reading. To demonstrate the validity of this procedure, we have made certain spectrophotometric studies of solutions of bilirubin, urine, and bilirubin in urine.

If a sample of urine from a jaundiced patient is treated with caffeine sodio-benzoate, diazobenzenesulfonic acid in hydrochloric acid solution,* and is buffered to a final pH of 4 to 5.5, a definite red tint appears. The spectrophotometric comparison of such a solution with water in terms of percentage of light transmitted at various wave lengths is shown in Fig. 1 (curve a). A similar comparison of the same urine treated with caffeine sodio-benzoate, buffer, and an amount of hydrochloric acid equivalent to that in the diazo reagent (that is, the "blank" solution already described) is shown in Fig. 1 (curve b). The sample to which diazo reagent has been added transmits much less light in the

*Hereinafter designated the "diazo reagent."

region between 500 and 600 $m\mu$ than does the untreated sample. In the region between 450 and 520 $m\mu$, however, various urinary pigments cause a considerable reduction in the light transmitted by the untreated sample. An allowance for this absorption, common to the two samples, is made by comparing the sample to which the diazo reagent has been added with the sample untreated (except for identical acidification, buffering and dilution), instead of with water. The resulting percentage transmission of light at various wave lengths is shown in Fig. 1 (curve *c*); there has appeared, as the result of the addition of the diazo reagent, a distinct zone of increased spectral absorption with a maximal value between 520 and 540 $m\mu$. The spectrophotometric measurement of the light transmitted by a solution of purified bilirubin treated with the diazo reagent in a mixture of chloroform, alcohol, and water is represented in Fig. 1 (curve *d*) and is essentially identical in character and spectral region of maximal absorption with that represented in Fig. 1 (curve *c*).

Fig. 1.—Spectrophotometric transmission curves: *a*, of urine (diluted 1:4) from a jaundiced patient after the addition of acetate buffer, diazo reagent, and water, compared with water as a standard; *b*, of urine (diluted 1:4) from the same sample after the addition of acetate buffer, acid blank solution, and water, compared with water as a standard; *c*, of the solution represented by curve *a* when compared with the solution represented by curve *b* instead of water as a standard; *d*, of pure bilirubin dissolved in chloroform, diluted with alcohol, treated with the diazo reagent, and compared with water.

In Fig. 2 (curve *a*) is shown the spectrophotometric curve of light transmitted by a mixture of phosphate buffer, alcohol, diazo reagent, and bilirubin dissolved in sodium carbonate solution (compared with water). A portion of the same sample of bilirubin dissolved in sodium carbonate solution was added to normal urine. A portion of the resulting mixture was treated with caffeine sodio-benzoate, buffer, and the diazo reagent, and was compared spectrophotometrically with another portion of the mixture treated with caffeine sodio-benzoate, buffer, and hydrochloric acid only. Fig. 2 (curve *b*) shows the percentage transmission of light then obtained at various wave lengths. Both the spectrophotometric curves obtained for bilirubin in chloroform and carbonate solutions after treatment with the diazo reagent, and the curve obtained after adding the same re-

agent to bilirubin in urine (using the untreated urine as a standard) are of the same general character and exhibit the same zone of absorption, with maximal absorption at 520 to 540 $m\mu$.

Fig. 2.—Spectrophotometric transmission curves; a, obtained when bilirubin dissolved in a solution of sodium carbonate is treated with the diazo reagent in the presence of phosphate buffer (pH 6.6) and alcohol, and compared with water as a standard; b, obtained when a mixture of normal urine and bilirubin dissolved in a solution of sodium carbonate is treated with caffeine sodio-benzoate, phosphate buffer, and diazo reagent, and compared with the same mixture treated with caffeine sodio-benzoate, phosphate buffer, and acid blank solution as a standard. Curve c represents the percentage of incident light transmitted at various wave lengths by the photometer filter used in these experiments.

Fig. 3.—Spectrophotometric transmission curves; a, of urine from a jaundiced patient, treated with caffeine sodio-benzoate, phosphate buffer, and acid blank solution, as described in the text, and compared with water as a standard; b, of a sample of the same urine treated with caffeine sodio-benzoate, phosphate buffer, and diazo reagent, as described in the text, and compared with water as a standard; c, of the solution represented by curve b when compared with curve a, instead of water, as a standard.

Oxyhemoglobin has bands of spectral absorption with their maximal values at 542 and 578 $m\mu$, respectively, and, therefore, it might be presumed that blood would interfere with the photometric determination of bilirubin. A specimen of urine from a jaundiced patient was divided into two portions: to the first

*Intact erythrocytes, of course, would be removed by centrifugation, along with other debris, from any sample ordinarily submitted to the test.

was added a quantity of hemolyzed blood,* and to the second an exactly equal amount of distilled water. The curves of Figs. 3 and 4 show how the use of the untreated urine blank compensates for the presence of added hemoglobin. In Fig. 3 curve *a* represents the spectrophotometric transmission of the portion diluted with water, prepared as for the "blank" solution, and compared with water; curve *b* contains the data on the same sample after treatment with the diazo reagent as already described; and curve *c* shows the resultant percentage transmission of light when the treated urine is compared with the untreated urine as a standard. In Fig. 4 curve *a* represents the spectrophotometric transmission

Fig. 4.—Spectrophotometric transmission curves: *a*, of urine from a jaundiced patient (the same sample as used for the curves of Fig. 3), with added hemolyzed blood, treated with caffeine sodio-benzoate, phosphate buffer, and acid blank solution, and compared with water as a standard, *b*, of the same urine-hemolyzed blood mixture treated with caffeine sodio-benzoate, phosphate buffer, and diazo reagent, and compared with water as a standard, *c*, of the solution represented by curve *b* when compared with the solution represented by curve *a* as a standard, instead of with water.

for the portion to which the hemolyzed blood was added and demonstrates the typical absorption curve of oxyhemoglobin superimposed on that of the urine alone; curve *b* represents the spectrophotometric transmission of the urine-hemoglobin mixture after the addition of the diazo reagent (compared with water); and curve *c* represents the spectrophotometric transmission of the urine-hemoglobin-diazo mixture compared with the untreated urine-hemoglobin mixture. It is obvious that curve *c* in Fig. 4 is essentially identical with curve *c* in Fig. 3.

Specimens of urine from several jaundiced patients were divided and treated as just described, and were then assayed for bilirubin in the photometer. The data are presented in Table I; they clearly demonstrate that the added hemolyzed blood does not impair the accuracy of our method.

We have shown by the foregoing experiments (a) that the development of typical diazobilirubin is not hindered by urinary constituents, and (b) that under the conditions which we have specified, diazobenzenesulfonic acid does not couple with urinary constituents other than bilirubin to produce a colored substance having a zone of absorption in the region between 500 and 600 $m\mu$. We have also shown that pre-existing urinary pigments which produce some absorp-

tion in the spectral region with which we are concerned (that is, 520 to 540 $m\mu$) are entirely compensated for by the use of the diluted acidified urine, untreated with the diazo reagent, as a standard for spectrophotometric or photometric comparison.

TABLE I
EFFECT OF ADDING HEMOLYZED BLOOD TO URINE

NUMBER	MILLIGRAMS OF BILIRUBIN PER 100 ML. OF	
	URINE	URINE + HEMOLYZED BLOOD
1	3.20	3.20
2	1.30	1.35
3	0.70	0.70
4	1.03	1.03
5	1.70	1.65

When spectrophotometric determinations are made of the transmissions of normal urine before (Fig. 5, curve *a*) and after (Fig. 5, curve *b*) treatment with the diazo reagent, both identically diluted and compared with water, it is again apparent, as in the case of urine from a jaundiced patient (Fig. 1, curves *a* and *b*) that there is a greater absorption of light in the region of the shorter wave lengths after the addition of the diazo reagent. When the sample to which the diazo reagent has been added is compared spectrophotometrically with the untreated sample, however, no characteristic band of absorption appears (Fig. 5, curve *c*). This is probably due to an overshadowing effect of the unchanged urinary pigments. Since the photometer deletes the effect of the increased absorption which appears to be produced in the deep blue region, this may be disregarded. We know of no other naturally occurring substance in the urine which could react with the diazo reagent under these circumstances to develop the color characteristic of diazobilirubin. Because the transmission curves for the normal urine coupled with the diazo reagent are themselves inconclusive, and because with larger amounts of bilirubin the characteristic absorption band of diazobilirubin develops, we are justified in the conclusion that the maximal absorption of light in the region of 520 to 540 $m\mu$ which occurs in urine treated with diazobenzenesulfonic acid as already described is due to bilirubin.

The importance of maintaining an acid reaction when assaying urine for bilirubin as we have described follows from a consideration of the coupling reactions known to occur with diazobenzenesulfonic acid in sodium carbonate solution. This reaction was introduced by Panly, and together with its modifications has been extensively applied by a number of investigators (Clifford,⁸ Hanke and Koessler,¹⁰ Hunter,^{6, 7} Nakayama,¹³ Hewitt, and others) to many substances, notably the phenols, imidazoles, and certain amino acids. Several of these are included among the seventy possible urinary constituents described by Thierfelder. A few of them, biliverdin, urobilin (Ehrlich), xanthine, hypoxanthine, guanine (Hunter⁶), phenol, and histamine have been specifically tested with the diazobenzenesulfonic acid reagent in acid solution and have been found to produce no color which could interfere with the test for bilirubin. Hunter⁷ stated that aromatic amines (of which there are none in Thierfelder's list) will react

with diazobenzenesulfonic acid in acid solution, but he added that "there has never been any question of its specificity in biological fluids for bilirubin." We feel that this conclusion is strongly confirmed by the spectrophotometric curves which we have presented.

Fig. 5.—Spectrophotometric transmission curves: *a*, of normal urine treated with caffeine acid blank solution, and compared with water as a standard; *b*, of normal urine treated with caffeine sodio-benzoate, phosphate buffer, and the diazo as a standard; *c*, of the solution represented by curve *b* compared with curve *a* as a standard, instead of water.

Fig. 6.—Curves representing postoperative fall in total serum bilirubin and urinary bilirubin, expressed in milligrams per 100 ml., over a period of time measured in days. The data were obtained from a case of obstructive jaundice due to carcinoma of the head of the pancreas. The serum bilirubin values were determined by the method of Malloy and Evelyn.

The "Ehrlich diazo reaction," as described in current texts on clinical pathology (for instance, Todd and Sanford), is made in ammoniacal solution. Just what substance produces the test is not definitely known, although it has been studied by Hunter,⁷ Sachs and Schmidinger, Miyazaki, and Nakayama. What we have said about the Pauly reaction applies equally well to the "Ehrlich diazo reaction."

The phosphate buffer which we have included in our reaction mixture serves chiefly to prevent the coagulation of albumin by the acid diazo reagent and to maintain the final pH in the range (4 to 5.5) most favorable for the characteristic red color of diazobilirubin.

Although alcohol is generally relied on to insure complete coupling of the diazo reagent with bilirubin in blood serum, it is unsatisfactory for this purpose in urine, because hazy solutions usually result, even though there be no precipitation of albumin, and in many instances the development of color is inhibited.

TABLE II

ACTION OF ALCOHOL ON THE DEVELOPMENT OF DIAZOBILIRUBIN COLOR IN URINE
(Values expressed in milligrams per 100 ml. of urine)

METHOD	NUMBER	DILUTION	
		WITH ALCOHOL	WITH WATER
I	1	0.27	0.47
	2	0.29	0.43
	3	0.15	0.33
	4	0.35	0.12
	5	0.51	0.53
	6	0.51	0.53
	7	0.13	0.63
	8	0.24	0.37
	9	0.31	0.45
	10	0.08	0.15
II	11	0.03	0.07
	11a	0.15	0.38
	11b*	0.08	0.43
	12	0.31	0.49
	13	0.43	0.33
III	14	0.43	0.78
	15	0.37	0.43
	16	0.40	0.47
	17	0.26	0.38
	18	0.36	0.48

Method I: 5 ml. of methanol or water plus 1 ml. of diazo reagent (or acid blank solution), plus 4 ml. of urine; centrifuge.

Method II: same as Method I, except that the urine was acidified with hydrochloric acid to pH 5.5 to 6 before adding the test solutions.

Method III: 2 ml. of centrifuged urine, plus 2 ml. of phosphate buffer pH 6.6; plus 1 ml. of diazo reagent (or acid blank solution), plus 5 ml. of water or methanol.

*Buffered to pH 6.6 with phosphate buffer before the test.

The generally higher values of the aqueous solutions shown in Table II probably reflect the greater accelerating action of urea, which Adler and Strauss discovered in an effort to determine the nature of the "direct" and "indirect" van den Bergh reactions in blood serum. They found that caffeine sodio-benzoate, urea, and certain other diuretic substances greatly accelerated the development of a maximal degree of color by the diazobenzenesulfonic acid coupling reaction with bilirubin. Caffeine sodio-benzoate in 25 per cent solution can be added to urine without the formation of a precipitate and, as shown in Table III, frequently aids in the development of the maximal depth of color and in the prevention of haziness. Fig. 2 (curve *b*) shows that this color is the same as the color developed in other solutions which contain bilirubin. Because of the inevitable presence of urea in urine, the terms "direct" and "indirect" can have no significance as applied to urinary bilirubin.

TABLE III

EFFECT OF CAFFEINE SODIO-BENZOATE ON THE DEVELOPMENT OF DIAZOBILIRUBIN COLOR IN URINE
(Values expressed in milligrams of bilirubin per 100 ml. of urine.)

NUMBER	WITHOUT CAFFEINE	WITH CAFFEINE
19	0.30	0.55

*Average recovery 97.4 per cent; range 85.1 to 109.4 per cent.

†This solution became faintly hazy on the addition of the bilirubin to the urine.

The final test of any analytical procedure is the accuracy of its quantitative recovery of the test substance. The application of this inquiry to bilirubin in urine is vastly complicated by the virtual insolubility of bilirubin except in highly alkaline mixtures or in organic substances which are immiscible with water. After many experiments it was found that bilirubin dissolved in a solution of urea and sodium carbonate, a mixture* prepared and furnished through the generosity of Dr. David Klein, Director of the Wilson Laboratories, could be added to urine in most instances without precipitation and without making the solution sufficiently alkaline to invalidate the test. The procedure was as follows: 1 ml. of the diluted bilirubin solution was placed in each of two 10 ml. volumetric flasks, and was made up in the one instance with urine and in the other with distilled water to the volume of 10 ml. In a third 10 ml. volumetric flask were placed 1 ml. of distilled water and 9 ml. of urine. From each of these mixtures, 2 ml. were then taken for testing according to the method that we have described, the diluted urine being used as a "blank" for the urine alone and the urine plus bilirubin, and distilled water as the "blank" for the bilirubin

*The original mixture contained in each milliliter 22 mg. of bilirubin, 300 mg. of urea, and 10 mg. of sodium carbonate. This solution is made up at the rate of 300 mg. of urea and 22 mg. of bilirubin per 100 ml. The average daily excretion of urea in normal urine is such that a concentration of at least 1,000 mg. per 100 ml. is maintained. It may be that even though the urine is acid, the bilirubin excreted by the kidneys is held in solution in some way by the urea present.

alone. On the average, as shown by the results in Table IV, 97.4 per cent of the added bilirubin was recovered.

The test here described was developed in connection with certain experiments on the excretion of bilirubin in which a quantitation of urinary bilirubin seemed desirable. In Fig. 6 are shown the relative concentrations of serum bilirubin and urinary bilirubin from a patient whose obstructive jaundice was subsiding postoperatively.

SUMMARY

On the addition of an acid solution of diazobenzenesulfonic acid to urine that contains bilirubin, the typical color of diazobilirubin is developed. The use of a suitable phosphate buffer prevents the precipitation of albumin and maintains the pH of the reaction mixture in the zone between 4 and 5.5. Caffeine sodio-benzoate may be added to assure the development of the maximal depth of color and to aid in the prevention of haziness. It is emphasized that the Pauly reaction and the "Ehrlich diazo reaction" take place in alkaline solution.

Spectrophotometric curves show that the red color developed in urine on the addition of caffeine sodio-benzoate, phosphate buffer, and acid solution of diazobenzenesulfonic acid can be used to estimate bilirubin in the photometer, provided the instrument is standardized against a similarly diluted sample of the untreated urine.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

GRANULOMAS, Venereal and Non-Venereal of the Vulva, von Haam, E. J. A. M. A. 114: 291, 1940.

The macroscopic and microscopical pictures of 155 cases of infectious granulomas of the vulva were observed in the laboratory for venereal diseases in New Orleans.

Because of the fundamental difference in diagnosis and therapeutics, a subdivision of infectious granulomas into the groups of venereal and nonvenereal lesions is recommended.

The presence of several etiologic factors in one pudendal granuloma could be proved in 11 cases. Various tests for the correct diagnosis of granulomas of mixed etiology have been evaluated.

Proper treatment of a granuloma of the vulva should be deferred until a complete diagnosis of the lesion has been reached. This will be greatly facilitated by the liberal use of laboratory methods.

THYROID DISEASE, A New Diagnostic (Galactose) Test for, Althausen, T. L., Lockhart, J. C., and Soley, M. H. Am. J. M. Sc. 119: 342, 1940.

A new clinical test for activity of the thyroid gland based on the rate of intestinal absorption of galactose is described. It consists of oral administration of galactose followed by determinations of galactose in the blood thirty and sixty minutes later.

Data from 121 control subjects and 130 patients with hyperthyroidism show that the average maximal concentration of galactose in the blood of patients with hyperthyroidism was three times greater than normal and that clinically the test was comparable in reliability to estimations of the basal metabolic rate.

Following thyroidectomy, the galactose tolerance test was normal in almost all cases.

Advantages of the galactose test are that it is more sensitive than the basal metabolic rate in cases of low-grade hyperthyroidism, and that its outcome is not influenced by hyperventilation in anxiety states or by cardiac dyspnea. A disadvantage of the test is that the presence of hepatic insufficiency or of Paget's disease interferes with its use for the diagnosis of thyroid disease.

In myxedema abnormally low galactose tolerance curves were observed, indicating that the galactose test can be used also in the diagnosis of this condition.

The technique of the test follows:

Forty grams of galactose (Pfanstiehl) dissolved in 400 c.c. of water and flavored with lemon juice were administered by mouth after the patient had fasted overnight. Specimens of blood were obtained from the cubital vein before, and 5, 15, 30, 60, and 120 minutes* after administration of galactose.

The glucose fraction of the blood was removed by fermentation with ordinary yeast, according to the method of Somogyi as modified by Raymond and Blanco.

Preparation of Yeast.—A weighed amount of fresh commercial yeast (Fleischmann's) is suspended in 5 to 10 parts of water, centrifuged, and decanted. This is repeated until the supernatant liquid is clear and colorless and gives no reduction test (6 to 7 washings). The yeast is then suspended in 10 parts of water. In this condition it will keep in a refrigerator for about two weeks.

Use of the Hagedorn-Jensen Method.—Two-tenths cubic centimeter of blood is collected into an accurately calibrated pipette (the authors use 0.2 ml. in 0.001 ml. Kahn pipette).

*At present the authors consider the 15- and 120-minute specimens unnecessary, and the 5-minute specimen relatively unimportant, except when the test is repeated on account of borderline results.

No. 37036), and transferred to 2.3 c.c. of distilled water, rinsing the pipette once or twice with the solution. One cubic centimeter of the 10 per cent yeast suspension is then added, the contents are mixed by tapping the tube against the hand, and after four or five minutes 0.5 c.c. of tungstic acid solution (prepared freshly by mixing equal volumes of 10 per cent sodium tungstate and $\frac{2}{3}$ N sulfuric acid) is added. The test tube is covered with the thumb, and the contents are mixed quickly by inverting. After standing a few minutes, the mixture is centrifuged at high speed. One cubic centimeter of the clear filtrate is used for titration.

Use of the Folin-Wu Method.—The yeast is washed in the usual manner and a 20 per cent yeast suspension is prepared. To 2 c.c. of oxalated blood 14 c.c. of the yeast suspension and 4 c.c. of the tungstic acid solution are added. This mixture is filtered, and 2 c.c. portions of the filtrate are used for sugar determinations.

The figure for nonfermentable reducing substances in the fasting blood is subtracted from the corresponding figure in the remaining specimens to obtain the galactose content of the blood titrated as glucose. In order to obtain the true value for galactose, which has a lower reducing power than glucose, 24 per cent must be added to the last figure.

Galactose is used in this test because, while having a rate of absorption very similar to that of glucose, it has the advantage that, unlike glucose, it can be identified in the blood.

HEMATURIA, Diagnostic Value of Occult, Barach, J. H., and Pennock, L. L. J. A. M. A. 114: 640, 1940.

Orthotolidine is a sensitive test for occult hematuria. A positive orthotolidine reaction was found in one-third of 681 general medical cases of the so-called chronic diseases. It is less common in youth, with more intact vessels, and it is more common in females than in males on account of the greater source of bleeding in the female generative tract. Seasonal variation pointed to the highest incidence during the summer months. Albuminuria and occult blood are found independently of each other, each having its own significance. Glycosuria is not a cause of occult bleeding. Arsenicals in therapeutic doses do not cause occult bleeding. Alkalinity or acidity of the urine is not a cause of occult bleeding. In patients showing persistent occult hematuria, hypochromic anemia is common. A review of the type of case in which the strongest reactions occurred reveals that these reactions were most pronounced in the clinically recognized serious types of disease and that the test reflects the patient's actual condition.

STREPTOCOCCI, Human Hemolytic From Diseases of Children, Boisvert, P. L. Am. J. Dis. Child. 59: 281, 1940.

The Lancefield group precipitin test gave consistent results and seems well adapted for epidemiologic use. The results suggest that infants and children are no more, and may be less, susceptible than adults to infection by hemolytic streptococci or groups other than A. It seems significant to the author that during a period of over a year all the strains of hemolytic streptococcal infections and their possible sequelae should belong in the one group, group A. Thus, 509 strains of group A hemolytic streptococci were consecutively obtained from 262 pediatric patients.

Infants and children are no more susceptible than adults to infection by hemolytic streptococci of groups other than A.

This study is being continued and is now in its fourth year. The only exception to date is the isolation this fall of a group F hemolytic streptococcus from the blood of a 7-year-old child with a nonfatal septicemia.

PERICARDIUM, Milk Spots, Nelson, A. A. Arch. Path. 29: 256, 1940.

Pericardial milk spots occurred in 170 (24.4 per cent) of 494 persons 1 year or more of age. In 439 persons 18 or more years of age the incidence was 37.6 per cent. In general, there is an increase of incidence with age, but this increase is by no means rectilinear. The spots are scarce in children and very frequent in old age, but between 35 and 75 years of age there is little change in incidence.

There seems to be a definite association with chronic or recurrent valvular heart disease; of 42 persons with such disease, 28 (66.7 per cent) showed spots. Patients with severe coronary sclerosis and enlarged hearts showed fairly definite increases (50.0 and 47.9 per cent, respectively).

The occurrence of more than one spot is slightly more frequent than that of only one. Spots occur on the right side, anteriorly, and on the ventricles much more frequently than they do on the opposite surfaces.

Old pleural adhesions are slightly more frequent in patients with spots than in those without.

Fifteen or 20 per cent of spots show appearances (projecting villi, cellular exudation, subepithelial, palisading, or epithelial enclosures in collagenous tissue) which suggest transitions from a more active inflammatory process to the usual type of milk spot.

SULFAPYRIDINE THERAPY, Nature of the Renal Lesion With, Stryker, W. A. J. A. M. A. 114: 953, 1940.

Precipitation of acetylsulfapyridine in the kidney was found at autopsy of a patient after treatment with sulfapyridine. The marked dilatation of cortical tubules and glomerular spaces, characteristic of kidneys in cases of sulfapyridine toxicity, seems to depend on intratubular precipitation of the drug or its compounds. There is a possible explanation for the previous difficulty in demonstrating the material in histologic sections.

DEXTROSE TOLERANCE, Tests of the New Born, Ketteringham, R. C. Am. J. Dis. Child. 59: 542, 1940.

By the Jeghers-Myers modification of the Folin-Mahros ferricyanide micromethod, the blood sugar values of 16 normal newborn infants, 5 to 10 days old, ranged from 70 to 95 mg. per hundred cubic centimeters three and one-half to four hours after feeding, with a mean of 81 mg.

Dextrose tolerance tests were made on 15 normal infants. Oral administration of 1.75 Gm. of dextrose per kilogram of body weight, as a 10 per cent solution, with blood sugar determinations one-half, one, two, three, and four hours after the midpoint of the period necessary for ingestion, produced an average maximum level of 145 mg. per hundred cubic centimeters. Two distinct curves were present; the blood sugar value of formula-fed infants reached a mean maximum of 143.2 mg. at thirty minutes, while that of breast-fed infants reached a mean maximum of 142.6 mg. at one hour.

Response to the dextrose meal was higher than in previously reported work; apparently these infants responded just as young adults do. The hypoglycemic reaction of Foster was encountered in 11 of the 14 babies tested.

Infants of diabetic mothers were more difficult to test than were the controls, and the curves produced seemed less reliable than those of the controls, owing to technical factors which could not be regulated. One infant who had previously showed the clinical signs of hypoglycemia had a strikingly erratic curve.

The Exton-Rose one hour, two-dose test, modified to the dose-weight principle, was administered to 3 normal infants, but the nature of the divided dose leads one to believe this technique unsuitable for the newborn.

GNORRHEA, Culture Method in the Diagnosis of, A New Medium, Pitts, A. C. Ven. Dis. Inform. 21: 67, 1940.

A relatively simple medium for the culturing of gonococci has been described.

This medium is a variation of the Schwartz-Davis medium and consists of a testicular infusion agar to which sterile hydrocele, ascitic, or pleural fluid is added. It has proved a most satisfactory medium for primary cultures.

The preparation of the medium follows:

Infuse 500 Gm. of minced sheep testicles in 1 liter of distilled water overnight in the icebox. (The testicles should be from recently killed animals.) Strain through gauze, boil vigorously for one-half hour, and strain through gauze again. Restore volume with distilled water and boil another one-half hour to complete coagulation, strain through gauze and

filter through paper. If coagulation is complete, filtration will be relatively easy by the use of suction; if coagulation is not complete, it is advisable to boil the infusion a little longer. Restore volume and add:

20 Gm. bacto-peptone
5 Gm. sodium chloride
5 Gm. dextrose

Adjust the reaction to pH 7.8 (pH should be between 7.4 and 7.6 after autoclaving) and add:

20 Gm. bacto-agar

Heat until agar is melted (autoclaving the mixture twenty minutes is a satisfactory method), filter through gauze and cotton, and tube approximately 5 c.c. per tube. Autoclave for thirty minutes at 10 pounds' pressure. When cooled to 50° C., add approximately 2 c.c. of sterile hydrocele fluid, rotate the tube to insure an even mixture, and slant. As soon as the agar is hardened, replace the cotton stoppers with rubber ones; it is important to do this as soon as possible in order to retain a maximum amount of moisture in the tubes. This medium will keep in the incubator for several months.

UREA, Rapid Methods for the Determination of, in Blood and Urine, Scott, L. D. Brit. J. Exper. Path. 21: 93, 1940.

1. Centrifuge tubes graduated at 5 c.c., and thick-walled test tubes of approximately 6 by $\frac{5}{8}$ inches.
2. Pipettes of 0.2 c.c., 1 c.c., 2.5 c.c., and 5 c.c. capacity.
3. Two 5 c.c. microburettes graduated to 0.05 c.c.
4. N/20 and N/100 sulfuric acid.
5. Approximately N/50 sodium hydroxide.
6. No. 1 Whatman filter papers of 5.5 cm. diameter.
7. Absolute alcohol and redistilled or "Analar" acetone.
8. Special mixed indicator:

Stock Solution A: 0.02 per cent methyl red in 60 per cent (by volume) absolute alcohol. The solid methyl red should be ground up with absolute alcohol in a small mortar till completely dissolved, and transferred to the 100 c.c. flask by repeated washings with absolute alcohol in the usual manner. Forty cubic centimeters of water are added and the volume is brought to 100 c.c. with absolute alcohol.

Stock Solution B: 0.10 per cent aqueous methylene blue.

The indicator is prepared by adding 1 c.c. of the methylene blue (solution B) to 15 c.c. of methyl red (solution A). The mixture, if green in color, is brought to a very faintly acid reaction by adding N/10 hydrochloric acid drop by drop with constant shaking until the solution just turns reddish purple. This solution keeps indefinitely if stored in an amber ground glass-stoppered bottle. It is reddish purple in acid solution, and bright green in alkaline solutions.

9. Neutral "Urease-Dunning" enzyme suspension:

Four 25 mg. tablets of "Urease-Dunning" are thoroughly ground up in a small mortar with 4.5 c.c. of N/100 sulfuric acid. When an even emulsion has been obtained, 0.2 c.c. of the mixed indicator is added. The extract, if correctly prepared, has a grayish buff coloration (the neutral point of the indicator) and keeps in the refrigerator for one month.

Determination of Urea in Blood.—Into one of the 5 c.c. graduated centrifuge tubes, containing 3 to 4 c.c. of absolute alcohol or acetone, pipette 1 c.c. of serum, oxalated whole blood, or plasma. As it is impossible to remove the last traces of blood from the pipette by sucking up and blowing out with alcohol in the usual manner (due to the pipette becoming clogged with precipitated blood protein), the pipette must be allowed to drain thoroughly for about one minute, and the last traces of blood removed by expelling the air. By this procedure not more than 0.01 c.c. of blood is retained in the pipette. The centrifuge tube is now securely stoppered and vigorously shaken, after which the volume is readjusted to 5 c.c. by the further addition of a few drops of absolute alcohol or acetone, as the case may be, to counteract the reduction in volume due to the formation of alcoholic hydrates. Mix again by shaking well and centrifuge at high speed for two to three minutes, or filter

through a No. 1, 5.5 cm. paper. After filtration the precipitated blood protein contained in the filter paper should be disturbed by very gentle stirring with a small glass rod, otherwise the 2.5 c.c. of filtrate may not always be obtained from bloods rich in metaprotein. Measure 2.5 c.c. of supernatant fluid or filtrate into one of the thick-walled test tubes and add 3.5 c.c. of water. The alcoholic extract becomes slightly opalescent due to the partial precipitation of blood fat by the lowered alcoholic concentration. Three-tenths cubic centimeter of special indicator is added and the alkaline reaction (green) brought over to the acid side (reddish purple) by the addition of N/20 sulfuric acid, with thorough mixing after the addition of each drop. The alcoholic extract varies in alkalinity according to the blood bicarbonate content. Fiftieth-normal sodium hydroxide is carefully added until the reaction is just alkaline again, and the reaction finally brought over to the very faintly acid point of the indicator by the addition of N/100 sulfuric acid, drop by drop, with constant shaking. By this readjustment of the pH, final titration with relatively strong acid is avoided, enabling the starting point of the reaction to be controlled to within one drop of N/100 sulfuric acid, which in terms of blood urea is approximately 1 mg. per 100 c.c. Finally, 0.35 c.c. of well-shaken neutral urease suspension is added, and after thorough mixing, the tube is securely stoppered and heated in the water bath at 50° to 55° C. for ten to fifteen minutes. Remove the tube from the bath and titrate with N/100 sulfuric acid until slightly acid (the original reddish purple starting point of the reaction). The titration value in cubic centimeters multiplied by 60 equals milligrams of urea per 100 c.c. of blood.

Determination of Urea in Urine.—For the estimation of urea in urine a 1:50 dilution of the specimen is made with distilled water (with small quantities of urine 0.2 c.c. can be measured with a blood pipette into 9.8 c.c. of water) and after mixing well, 5 c.c. is pipetted into a thick-walled test tube and 0.3 c.c. of indicator is added. The faint greenish coloration obtained with the majority of urines is due to the urine being alkaline to the special indicator. Adjustment is made to the faintly acid side of the indicator by the addition of N/100 sulfuric acid drop by drop. One-half cubic centimeter of well-shaken neutral urease suspension is now added, the tube is securely stoppered, and the mixture (which turns green almost immediately) is heated in the water bath at 50° to 55° C. for five minutes. The ammonium carbonate so formed is back titrated with N/20 sulfuric acid till just reddish purple, i.e., the original starting point of the reaction. The titration value in cubic centimeters multiplied by 1.5 equals grams of urea per 100 c.c. of urine.

BLOOD, A Familial Hematopoietic Disorder in Italian Adolescents and Adults, Wintrobe, M. M., Matthews, E., Pollack, R., and Dobyns, B. M. J. A. M. A. 114: 1530, 1940.

Fourteen individuals, members of three Italian families representing three generations in one family and two in another, have been examined and have been found to have certain abnormalities.

In four marked poikilocytosis, microcytosis, hypochromia, and stippling of the red blood cells as well as corpuscles resembling targets were observed. In addition, there were increased resistance of the red corpuscles to the hemolytic action of hypotonic saline solutions, splenomegaly, and bilirubinemia or urobilinuria. One of these patients also had erythroblastosis in the sternal bone marrow and slight osteoporosis.

In four persons all the abnormalities mentioned except splenomegaly were found. In two children there was slight splenic enlargement without significant changes in the blood. Of the remaining four persons, all females, there was microcytosis without other significant changes in two, and slight macrocytosis as well as stippling in two.

This disorder may be considered to be a benign form of Cooley's anemia or Mediterranean disease.

This condition and Cooley's anemia appear to be the result of an inherited defect in the production of red corpuscles whereby corpuscles are formed with an adequate or excessive membrane which contains little substance. As a result the cells can withstand the hemolyzing effect of hypotonic saline solutions more readily than normal cells. The other characteristics of the disorder are explained by the assumption that they are due to attempts to compensate for the faulty red blood cell formation.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

The Fundamentals of Internal Medicine*

DESIGNED primarily for the introduction of students to the study of internal medicine, this volume, nevertheless, contains good chapters dealing with otolaryngology, ophthalmology, and dermatology. Because photographs of dermatoses show up better in white persons than in Negroes, it is felt that the section on dermatology would be improved by changing such illustrations. A chapter on dietetics is also provided.

The work is intended to provide the foundation upon which the superstructure of more detailed and extensive knowledge may be built. In this aim it succeeds admirably.

Cancer†

THIS volume was prepared by a committee representing the Massachusetts Medical Society and the American Society for the Control of Cancer. It is intended for the general practitioner and is designed to aid him in the diagnosis of early cancer and to suggest the treatment recognized at the present time. Chapters on cancer of the various organs are written by men especially interested in the subject.

The discussion of the care of the patient with advanced cancer, and neurologic methods of relief of pain are also handled in an able manner.

The various organizations for the control of cancer, local and national, are described. There is a concluding chapter on suggestions for talks on cancer to lay audiences.

The book is brief and is not intended to take the place of the more extensive treatises in the field.

It is felt that this is excellent propaganda, using the word in its best sense.

Manson's Tropical Diseases‡

PROBABLY the outstanding text in its field, this book has now come into the eleventh edition. Although the term "tropical medicine" is in general usage, it is perhaps a misnomer. One has only to recall the Chicago outbreak of amebiasis, the cases of malaria in

Medicine. By Wallace Mason Yater, A.B., M.D., M.S. and Director of the Department of Medicine, Georgetown University Hospital; Physician-in-Chief, Georgetown University Hospital; Washington, D. C. Formerly Fellow in Medicine, the Johns Hopkins Hospital. D. Appleton-Century Company, Inc. Cloth, 1,021 pages.

†Cancer—A Manual For Practitioners. The Committee on Publication: George W. Holmes, M.D., Chairman; Ernest M. Daland, M.D.; Shields Warren, M.D.; and Channing C. Simmons, M.D., Editor. Cloth, 284 pages. Boston, Mass., 1940.

‡Manson's Tropical Diseases. A Manual of the Diseases of Warm Climates. Edited by Philip H. Manson-Bahr, C.M.G., D.S.O., M.A., M.D., D.T.M.; and H. Cantab, F.R.C.P. London, Senior Physician to the Hospital for Tropical Diseases, London, the Albert Dock Hospital and the Tilbury Hospital; and the Colonial Office and Crown Agents for the Colonies; and the Royal Air Force; Director, Division of Clinical Medicine, Tropical Medicine to the I. North-Eastern Post-Graduate School of Medicine; Member of the Council of the Conjoint Board of the Royal College of Physicians, London, and to Cambridge and Work of Sir Patrick Manson, 1927; and "The Dysenteric Disorders," 1930. Cloth, ed. 11, revised, 1,043 pages, 18 color plates, 15 halftone plates, 364 illustrations in text, 6 maps, and 28 charts, \$11.00. A William Wood & Co. book. Williams & Wilkins Co., Baltimore, Md., 1940.

narcotic addicts, the widespread incidence of intestinal parasites, and the great amount of bacillary dysentery, to realize that we have many "tropical" diseases in this country. In addition to a standard description of these and many other diseases, the book contains a section on life in the tropics of great value to anyone contemplating a trip or an extended sojourn into tropical climates. Anyone called upon to give advice to such persons will not be disappointed if he seeks information at this source.

Clinical Diabetes Mellitus and Hyperinsulinism*

IN THIS easily readable book the author has limited himself to clinical considerations describing procedure which in his extensive experience has proved most effective in the recognition and treatment of diabetes mellitus and its complications. Extended consideration of the theory of carbohydrate metabolism, the physiology of experimental diabetes, and the pathology of diabetes are omitted.

Description of techniques of diagnosis, diet, and insulin (old and new) is given in sufficient, but not excessive, detail. Much attention is directed toward the ills which so often are concomitant. Chapters are devoted to surgical operations and to pregnancy in diabetes.

A thorough section is afforded to hyperinsulinism in the last part of the book. There is a good bibliography and index.

Principles of Hematology†

IT IS pointed out that the symptoms of blood disorders do not help greatly in differentiation. An anemia from any cause will result in weakness, pallor, and palpitation of the heart. There may be fever, anorexia, dizziness, and edema. Few of the anemias have characteristic accompanying symptoms, with the striking exception of pernicious anemia. There are few characteristic symptoms of leucemia. The disease may be suspected from a splenomegaly, enlarged glands, fever, unexplained anemia, or abnormal bleeding. A careful history may reveal the explanation of an anemia, such as a previous blood loss or an acute or chronic infection. A thorough physical examination may reveal a malignancy.

Written by an outstanding hematologist, the book is well balanced. The anatomy and physiology of the blood, the mechanisms involved in the various dyscrasias, the techniques of blood examination, and finally treatment, are all excellently integrated.

Haden, M.A., M.D., Chief of the Medical Division of the Cleveland Clinic, Cleveland, Ohio; Professor of Experimental Medicine in the University of Kansas School of Medicine. Cloth, ed. 2, thoroughly revised, 362 pages, with 104 illustrative cases including 173 original photomicrographs and 100 original charts and drawings. Lea & Febiger, Philadelphia, 1940.

EDITORIAL

Clinical Chemistry

A NEW section on Clinical Chemistry is being inaugurated with this issue of the JOURNAL. This does not mean that the original scope of the JOURNAL, as defined by its first Editor, Dr. Victor C. Vaughan,¹ in the first issue, has in any way been changed. In the quarter of a century that has elapsed, many important advances in medicine have been made, and chemistry has contributed a large number of them. This has resulted in a considerable increase in the number of papers which have been devoted to studies falling under the classification of clinical chemistry. For this reason, it now seems desirable to group these articles together under this special heading.

Dr. Vaughan unquestionably visualized the expansion in this field when he founded the JOURNAL, since he was a pioneer* in this country in the field of biochemistry and clinical chemistry—then called physiological chemistry and pathological chemistry, respectively. It is pertinent to note that the subject of blood chemistry was in its infancy in 1915 when this JOURNAL was founded. The expansion which has taken place in this field is typical of the expansion which has occurred in many other fields of biochemistry. Although the accomplishments in blood chemistry are probably no more spectacular or important than those which have taken place in the field of the vitamins or of the hormones, still blood chemistry requires much greater use of the clinical laboratory and has more far-reaching ramifications. The latter is well illustrated by the fact that the action of vitamin D is shown by studies of the inorganic phosphorus and calcium of the blood serum, while that of insulin requires the determination of the blood sugar.

Recently the methods of chemical blood analysis have been extended to tissue analysis; this will doubtless greatly expand the interpretations which can be made upon the basis of blood analysis alone. By utilizing some of these micromethods after still further refining them, Richards,² in particular, has been able to develop a sound theory of urinary secretion, thus placing our chemical tests of renal function upon a firmer foundation. Illustrative contributions in the field of clinical chemistry need not be further multiplied.

While this JOURNAL has had a hand in presenting some of the most important original contributions—for example, Banting and Best³ presented their initial report on insulin here, and Stanley Benedict⁴ reported the excretion of uric acid by the Dalmatian coach dog, thus permitting the extension of studies on purine metabolism previously restricted to man (and the anthropoid apes)—still its greatest service to medicine has been in bringing new practical tests to the clinical laboratory and in turn to the clinic. This is in accord with the title of the JOURNAL and Dr. Vaughan's first editorial,¹ which indicated that the

*Dr. Vaughan was appointed Instructor in Physiological Chemistry at the University of Michigan in 1876.

purpose of the JOURNAL was to try to bridge the gap between the laboratory worker and the clinic, so that the physician could intelligently utilize without unnecessary delay the new laboratory aids which were rapidly becoming available. This need is even greater today than it was twenty-five years ago.

Clinical chemistry may be defined as that part of biochemistry which finds use in the diagnosis, prognosis, and clinical management of disease. The JOURNAL will accept for the section on clinical chemistry original articles, including methods, which meet a reasonably broad interpretation of this specification. It is hoped that this new section will be found increasingly useful by internists and clinical chemists alike.

PROGRESS

A CRITICAL HISTOPATHOLOGIC STUDY*

FIFTY POST-MORTEM PATIENTS WITH CANCER SUBJECTED TO LOCAL OR
GENERALIZED REFRIGERATION COMPARED TO A SIMILAR CONTROL
GROUP OF 37 NONREFRIGERATED PATIENTS

MACHTELD E. SANO, M.D., AND LAWRENCE W. SMITH, M.D.
PHILADELPHIA, PA.

IN PREVIOUS reports¹ the several members of our group who have been working upon the problems of reduced temperatures as applied particularly to cancer and embryonal cell growth have recorded their preliminary observations and deductions in rather broad generalities. This has been done intentionally in order to arouse interest in hypothermy both as a possible therapeutic agent and as a new approach experimentally to our understanding of human physiology.

The purpose of this paper is to reinforce these earlier studies by a more detailed analysis of the pathologic material obtained from the first 50 cancer patients who had undergone varying periods of refrigeration, either local, general, or combined, and who subsequently died. As a control, a similar series of 37 patients with cancer who died without having received refrigeration has been studied comparably. In this latter group the only selective factor which has entered the picture has been an effort to choose persons with the same primary organ involvement as those in the refrigeration series.

As it works out the refrigeration group tended to include, as might be expected, more advanced cases. The autopsies were all done by the same staff members, so that the two groups are strictly comparable in respect to the interpretation of any abnormal findings. We are not concerned in this paper

*From the Departments of Pathology, Temple University School of Medicine and Hospital, Philadelphia.
Aided by a grant from the Clinical Research Foundation, Philadelphia.

with any of the clinical aspects of the cases other than statistical; i.e., age of patient, duration and extent of disease, location of primary tumor, former treatment, whether surgical, radiologic, or combined, and the time relationship of such treatments, recurrence, metastases, etc. From the standpoint of refrigeration, ideally we should like to collect sufficient data to be able to tell whether continuous application is of greater effect than when refrigeration is given on the divided or fractionated dose principle, whether it is the *total* number of hours or the depth to which the temperature is successfully lowered and maintained, or some combination of these various procedures, which is the most successful in producing regressive cell changes in tumor tissue. As it is, in a small series of this size the most we can hope to do is to divide the cases on the basis of total number of hours of refrigeration received.

Since the publication of our initial studies concerning the effect of cold upon cancer and embryonal cell growth, a very considerable amount of discussion has resulted. One of the more critical of the statements has intimated that the growth of cancer cells is not only *not* impaired by cold, but is even *accelerated* and results in a wider dissemination of metastases. True, the observations are based on animal experiments² rather than on clinical studies. However, we feel that it is most important to know whether such acceleration of growth does occur in human beings or to what degree it is indicated, as upon such information depends the clinical selection and conduct of our cases. It is to study such questions that the careful and critical analysis of these autopsied cases seems so important to us, groping as we are in a field which is as yet totally unexplored.

Even though time may prove that such acceleration of cell growth may occur ultimately with refrigeration, it will not exclude refrigeration as a possible therapeutic weapon any more than it will exclude x-ray or surgery in which such effects are well recognized as occurring at times. The most pessimistic among us cannot deny that hypothermy has helped solve the problem of intractable pain in our patients with cancer. Any therapeutic agent must be weighed seriously as to its relative advantages and disadvantages before it is either used or discarded. It is from this purely objective standpoint that we wish to present in tabular form the histopathologic findings in these initial 50 refrigeration patients who were autopsied and compare them with a similar nonrefrigerated series.

The patients fell into three major groups, and a fourth group made up of miscellaneous forms of cancer. The three principal groups were (1) mammary, (2) uterine-cervical, and (3) gastrointestinal carcinoma. The fourth group was composed of tumors from almost every other part of the body, including lung, liver, adrenal, bladder, prostate, testis, mouth, thyroid, bone, lymph nodes and brain, as well as two cases of acute leucemia.

Fifteen of the 50 patients received local refrigeration treatment only, and properly might be excluded from the series as a whole. The great majority of the patients received less than 150 hours of generalized refrigeration (i. e., 35 persons, or 60 per cent), the time ranging from 24 to 150 hours. Only 5 persons received more than 150 hours of general hypothermy in this earlier series, although in subsequent studies more than twice this time interval was

not infrequently employed. It should be noted also, that in this initial series of cases the temperature level in general was maintained between 86° and 90° F., whereas in the later cases temperatures of approximately 8° to 10° lower were employed. Thus, the further analysis of a larger series of cases studied in the lower temperature range and maintained at these lower levels for much longer periods of time may require the revision of our figures and lead to other interpretations than are possible with these data.

	Edema						

With these preliminary comments we will present the statistical data in tabular form, comparatively arranged in the several groups for convenience. In Table I 24 cases of advanced breast cancer are shown. These were chiefly of the "simplex" type and varied from extremely cellular, medullary lesions to equally extreme scirrhous cases. The age of the patients ranged from 32 to 56 years, those in the lower age group predominating. Of the 12 patients subjected to refrigeration, all but one received generalized hypothermy, this one received cold locally. The 12 control patients received the usual suppor-

tive and symptomatic treatment. Several instances of operative and radiologic intervention are included in this latter group. Each of the persons who was refrigerated came to the hospital because of intractable pain, after all possible surgical and irradiation therapy had been employed, and after opiates had become ineffective. The duration of the generalized refrigeration varied from 50 to 230 hours, and the temperature range was from 83° to 90° F, the average being about 87° F.

Table I gives us a certain amount of information, much of it negative in character, but nevertheless of some importance and significance in our efforts to evaluate the effect of reduced body temperatures upon the activity of cancerous cells. In the first place, it is obvious that the entire 24 patients represent a much more advanced stage of malignancy than the average admission group, as shown by the widespread metastases in comparison with the figures from world literature compiled by Henke and Lubarsch in their *Handbook of Pathology*, and the series of 423 cases of breast cancer analyzed by Ewing. The metastatic figure is even greater in the 12 persons given refrigeration than in the corresponding 12 control patients, showing 100 per cent lung and skeleton involvement as compared with 75 and 33 per cent, respectively. Furthermore, these metastases were all present at the time of admission. Comment upon their serial roentgen-ray studies will be made later in this discussion in relation to the entire 50 cases. Suffice it to say that from the data available, we have no evidence to suggest that the rate of growth of such metastatic foci is accelerated. On the contrary, in some few instances it actually seems retarded. However, in view of the advanced stage of the disease in this group of patients as a whole, it is not possible either to prove or to disprove whether hibernation does or does not increase the spread of metastases or even alter the rate of growth of such metastatic tissue within the relatively short span of life during which they were under observation.

TABLE II

RELATIONSHIP OF METASTASES (PULMONARY) TO DEVELOPMENT OF BRONCHOPNEUMONIA IN 24 PATIENTS WITH BREAST CANCER

GROUP	PATIENTS WITH METASTASES					PATIENTS WITH NO METASTASES				
	NO. WITH METASTASES	BRONCHOPNEUMONIA		NO PNEUMONIA		NO. WITHOUT METASTASES	BRONCHOPNEUMONIA		NO PNEUMONIA	
		NO.	%	NO.	%		NO.	%	NO.	%
Refrigerated	11	7	58.3	5	41.7	0	0	0	0	0
Nonrefrigerated	9	3	33.3	6	67.0	3	1	33.3	2	67

Aside from the question of metastases two other features of interest pathologically have been noted which relate (1) to the part played by the heart during refrigeration and (2) the incidence and importance of bronchopneumonia comparatively in the refrigerated and nonrefrigerated cases. Both of these questions will be discussed in greater detail later, in respect to the entire 87 cases. So far as myocardial failure is concerned there seems to be no significant difference between the two groups.

The incidence of bronchopneumonia requires more detailed analysis. There is one factor which seems possibly significant in influencing the occurrence of pneumonia in both the refrigerated and nonrefrigerated groups, viz., the

presence or absence of metastases. The series of patients with cancerous breast seem to be representative of this point, having a particularly high incidence of metastases because of their anatomic relationship. In Table II the data are presented with this in mind, and an attempt is made to correct statistically for the difference in pulmonary metastatic incidence in the two groups.

From these figures it can be stated that the presence of pulmonary metastases, as might well be anticipated, is apparently associated with a somewhat higher incidence of terminal bronchopneumonia in the refrigerated series of persons with breast cancer. It might be added that under such metastatic conditions, the pneumonic incidence appears to be somewhat greater in the cases maintained under generalized refrigeration for the more prolonged periods of time. In a series of cases as small as this we are not certain whether the differences are of such magnitude as to be statistically significant, but we have gained the impression that where such pulmonary metastases do exist one must recognize an added risk in recommending generalized refrigeration for any given case.

Skeleton	Metastasis	0	0	0	0		

The second group of patients, somewhat smaller in number, who had advanced squamous carcinoma of the cervix uteri, are analyzed in Table III in the same way as the patients with cancer of the breast were presented. Of

the five patients who received refrigeration, only three were given cold locally, while the other two required generalized refrigeration to control the pain. As might be expected, the incidence of metastases in this group of cases was much less than in the breast cases, and inasmuch as cold could be applied successfully locally at a much lower temperature range than that obtained by the generalized reduction of body temperature, it was the method of choice.

A series of ten patients with cervical carcinoma, analyzed in Table III, presents a totally different clinical problem than the patients with breast cancer. The disease is a local one, with regional extension of the tumor rather than distant metastasis. In only two cases were pulmonary metastases found, and in neither of these was pneumonia present terminally.

The third group, consisting of twelve persons with carcinoma of gastrointestinal tract, do not parallel each other quite as closely as the previous series, there being a slight preponderance of gastric cases in the nonrefrigerated series. Of the remaining five experimental cases, two were primary in the transverse colon, one in the sigmoid, one in the rectum, and one represented a peptic ulcer just below the pyloric ring which had undergone malignant degeneration and showed widespread metastasis. The analysis of this series is presented in Table IV.

	Metastasis	0	0	0	0		
Skeleton	Metastasis	0	0	0	0		

In this group of gastrointestinal cases of malignancy, all the experimental cases received both local and general refrigeration. The time of the latter ranged from 150 to 230 hours, a distinctly more prolonged technique on the average than that used in the breast group. Yet when we look at the figures relating to the incidence of bronchopneumonia in these cases, there is no significant difference between the refrigerated and the nonrefrigerated cases. Even the presence of lung metastases does not seem to be an unduly important factor in determining this complication, as less than half the cases in the series of cervical and gastrointestinal carcinoma with lung metastases demonstrated any evidence of bronchopneumonia at autopsy.

Another point to which attention should be called is the curious finding of occasional cases of acute pancreatic degeneration microscopically. This may be accompanied by a small amount of fat necrosis and hemorrhage, and thus become a grossly demonstrable process in rare instances, as has been observed in more recent cases than those subjected to analysis in this early series. We are inclined to feel that pancreatitis is another possible complication of generalized refrigeration. On the basis of Oppenheimer and McCravery's³ studies, which established the fact that circulation time is definitely slowed, this can be explained perhaps as being the result of tissue anoxia, thus permitting the escape and activation of the pancreatic enzymes. We are of the opinion, however, that careful following of the blood amylase of patients during "hibernation" precludes serious danger.

TABLE V

27 PATIENTS WITH MISCELLANEOUS MALIGNANCY SUBJECTED TO REFRIGERATION

CASE NO.	SITE OF PRIMARY TUMOR	DIAGNOSIS	REFRIGERATION PERIOD	
			GENERAL (HR.)	LOCAL
1	Adrenal	Hypernephroma, malignant	-	5 weeks
2	Antrum	Carcinoma, squamous cell	-	12 weeks
3	Antrum	Carcinoma, squamous cell	-	10 days
4	Auditory canal	Carcinoma, squamous cell	-	3 weeks
5	Bladder	Carcinoma, squamous cell	48	12 weeks
6	Bladder	Carcinoma, squamous cell	-	16 weeks
7	Blood	Leucemia, acute lymphatic	90	-
8	Blood	Leucemia, acute lymphatic	230	-
9	Bone (tibia)	Osteogenic sarcoma	90	-
10	Bone (sacrum)	Fibromyxosarcoma	-	200 days
11	Brain	Glioblastoma multiforme	-	3 weeks
12	Liver	Hepatoma malignant	90	-
13	Lung	Bronchiogenic carcinoma	24	3 days
14	Lung	Bronchiogenic carcinoma	90	1 day
15	Lymph node	Hodgkin's disease	120	-
16	Mediastinum	Lymphosarcoma	50	-
17	Pancreas	Adenocarcinoma—duct type	50	-
18	Prostate	Adenocarcinoma	-	6 weeks
19	Retroperitoneum	Fibromyxosarcoma	120	-
20	Retroperitoneum	Reticulo-cell sarcoma	24	-
21	Skin	Melanoma, amelanotic, malignant	120	-
22	Submaxillary	Adenocarcinoma	-	30 weeks
23	Testis	Choriocarcinoma	-	1 week
24	Thyroid	Adenocarcinoma	120	-
25	Tongue	Carcinoma, squamous cell	50	-
26	Tonsil	Carcinoma, squamous cell	24	-
27	Uterus	Adenocarcinoma—fundus	-	3 weeks

In presenting the remaining 27 cases, the data have been condensed so far as possible into comparable tabular form as in the previous groups. The cases, however, as shown in Table V, are almost entirely single instances of a very wide variety of neoplasms, selected in part on that very basis in order to have the opportunity of studying the effect of reduced temperatures upon as many types of malignant cells as possible. For that reason, it is obviously impossible to present statistical data in respect to any one of these various forms of malignant disease individually, but the composite figures appear to fit in with those of the three other series already presented.

DISCUSSION

At this point it seems well to recapitulate the major pathologic findings which this survey has disclosed, and to try to compare them in the refrigerated and nonrefrigerated series of patients. As has been commented upon in earlier papers, the persons who have been observed under refrigeration in this study were all advanced, terminal examples of malignancy. None of them, therefore, have had a survival period long enough to be of much significance in respect to the question of the effect of cold upon metastatic foci. The interest centers chiefly upon the immediate effects of cold on neoplastic cell growth and on various physiologic mechanisms, as evidenced by demonstrable histopathologic changes in the tissues of the several organ systems. To this end let us attempt to discuss the findings separately in those organs where such demonstrable pathology has been found to exist.

Heart.—As has been shown by others,⁴ as well as by our own studies,^{5,6} generalized reduction of body temperature is quite regularly accompanied by alterations in the electrocardiogram which suggest rather widespread myocardial involvement; i.e., a depression of the T-wave and prolongation of the Q-S interval.

Furthermore, occasional instances of sudden fall in blood pressure followed by heart failure, and associated with very acute myocardial degeneration at autopsy, led us to suspect that the slowed circulation might present a serious problem insofar as maintenance of the nutrition of the heart muscle was concerned. Analysis of the autopsy material in these cases under consideration has been somewhat reassuring in this respect. In the 50 patients subjected to refrigeration a total of 42 (84 per cent) have shown some degree of myocardial degeneration, by far the greater number of grades I and II. On the other hand, 35 (94 per cent) of the 37 control patients have shown similar changes, with a definitely higher proportion in the grades III and IV classification comparatively.

It is doubtful whether any real importance should be placed on these relatively minor differences of percentage, although the grading in each instance was done by three members of the department independently with only very few and minor discrepancies. Thus, it seems fair to state that there is no apparent or significant difference in the actual incidence of myocardial degeneration in the two groups.

Respiratory Tract.—In attempting to evaluate the data relating to the respiratory tract, one problem, that of the incidence and relationship of broncho-

pneumonia to refrigeration, is obviously paramount. We have already seen in presenting the figures from the group of patients with breast cancer that the existence of pulmonary metastases seemed to increase the likelihood of the development of a bronchopneumonia during generalized refrigeration. However, in the comparable series of cases of breast cancer in the nonrefrigerated group the percentage incidence of terminal bronchopneumonia was identical (67 per cent) in the metastatic and nonmetastatic cases.

	Metastasis	—	—	—	—	—	—	—	—

When we turn to a consideration of both entire series, including the patients with cancer of the breast, as is shown in Table VI(B), we find the total incidence of bronchopneumonia is practically the same; 60 per cent in the refrigerated group and 53 per cent in the nonrefrigerated group. It is interesting to try to break down these figures in the refrigerated group in respect both to the presence of metastases and to the amount of generalized refrigeration the patients received.

What conclusions, if any, can be drawn from these figures in respect to the relationship of refrigeration and pneumonia? We have seen from the control patients that there is a normal expectancy of at least 50 to 60 per

cent of pneumonia in terminal malignancy, and that there is no appreciable difference in incidence between the persons with and without pulmonary metastases.

In the experimental series of 50 cases there occurred a total of 32 cases of bronchopneumonia. However, we must exclude those cases which occurred in patients who received only local refrigeration, i.e., 9 cases, as these cases could more properly be included in the control group. It is interesting to note that of the 15 patients treated only locally the incidence of pneumonia remains at the 60 per cent average level.

Of the 23 cases of pneumonia which occurred in patients who underwent "hibernation," 13 (56 per cent), or only slightly over half showed the presence of metastases. If we exclude the 7 patients with breast cancer who had pneumonia, we find that only 6 of the remaining cases (or 37 per cent) had metastases. In comparing these several figures analyzed variously, one can only come to the conclusion that the presence of pulmonary metastases does not significantly change the incidence of bronchopneumonia among patients undergoing generalized refrigeration. Likewise (and this is the point which above all we have been interested in determining), if these statistics can be accepted as of real significance, then they all point inevitably to the conclusion that generalized reduction of body temperature ("hibernation") does not change the incidence of terminal pneumonia in patients suffering from advanced malignant disease.

Liver, Spleen, and Kidneys.—In grouping these abdominal viscera together for consideration, we are prompted by the fact that such changes as have been noted have all been strictly comparable. There appears to be a slightly higher incidence of the so-called "toxic" degenerative reversible type of reaction observed in the refrigerated group than in the nonrefrigerated group. In other words, the mild, nonspecific granular changes seen so commonly in the liver and kidneys have been noted about 10 to 15 per cent more frequently in patients who have undergone "hibernation" than in those who have not. However, one must take into consideration the pneumonic incidence in relation to these changes, the amount of absorption from degenerating tumor tissue, the presence of metastases, and so many other variable factors that it seems only reasonable to assume that such minor changes as have been noted are within normal limits of variability. Certainly they do not appear to be sufficiently marked to be of any clinical importance.

Pancreas.—In the pancreas, on the other hand, it is our impression that we have pathologic changes among the refrigerated group which do not have their counterpart in the nonrefrigerated group. We might add that subsequent cases have given additional support to this contribution. While the actual incidence of pancreatic degenerative and inflammatory changes is only 10 per cent, it seems significant that *no* such changes have been found in the control group. These changes range from grossly apparent foci of fat necrosis or hemorrhage or both, to similar lesions of much less magnitude, demonstrable only microscopically. In line with Rich and Duff's⁷ conclusions, and more recently those of Smyth,⁸ these instances of so-called pancreatitis seem to

offer further substantiation to the theory of a vascular or circulatory origin in the development of the degenerative process. We feel that the slowed rate of blood flow may well be instrumental in producing tissue anoxia, followed by the characteristic pathology of the parenchyma of the organ. It most certainly offers a new approach to the experimental study of the condition.

As has already been commented upon, the following of these patients during "hibernation" by daily blood amylase determinations, as suggested by our biochemist, Dr. R. H. Hamilton, is a prophylactic measure which we have carried out routinely in subsequent studies. We are sure that at least one incipient severe instance of pancreatitis was prevented by this means, the patient being taken out of refrigeration with the sudden rise of the blood amylase to 1,100 units and the symptoms subsequently subsiding with the return of the amylase to normal levels.

Adrenal Glands.—No comparable control figures are available in respect to the adrenal glands. In going over the gross autopsy findings seldom was any comment found about any pathologic changes in these organs. Unfortunately, as a result microscopic sections were available in only a few instances. In view of the tremendous importance which Selye⁹ places upon the adrenal glands in the defense mechanism of the body, it is to be regretted that more detailed studies are impossible. Medullary depletion and cortical hyperplasia, as described by Selye, have certainly been observed in a number of the refrigerated cases, but irregularly. In any subsequent study more careful attention should and will be paid to these organs.

Brain.—Particular attention has been focused clinically upon the central nervous system of these patients during hibernation. The complete failure to recall anything over the entire period, the dulling of the sensorium, the slowing-up of speech and understanding, the complete mental recovery with relief of pain and headache, and not infrequently the almost euphoric state which has been noted, have all stimulated the keenest interest in neuropathologic studies.

Of the 50 patients coming to autopsy, permission was obtained to examine the brains of 44. Metastasis was found in only three cases; hence this factor does not enter prominently into the picture. Eleven cases should perhaps be excluded as the patients had received only local cold therapy. This still leaves 33 patients to be considered: 11 of these received less than 50 hours of general refrigeration, 17 received from 50 to 150 hours, and 5 had from 150 to 230 hours of "hibernation."

Outstanding as the only grossly demonstrable pathologic finding in the entire series was the presence of edema, which it must be admitted is often a very difficult thing to estimate. However, edema was recorded in 12 patients who had been refrigerated, and in an additional 4 who had received only local cold therapy. There is an interesting similarity in the percentage figures of the incidence of edema in (1) the group as a whole as shown in Table VI(B), i.e., 32 per cent; (2) 12 of the 35 persons refrigerated, i.e., 34 per cent; and (3) 4 of the 15 persons who were not refrigerated, i.e., 27 per cent.

From these figures it is apparent that generalized refrigeration in itself does not seem to be a significant factor in producing cerebral edema. The duration of the refrigeration period likewise does not appear to be significant in respect to either the incidence or the severity of the edema. In fact, the greater proportion of the cases were found in the less than 50 hour group.

Microscopic study has failed to reveal any other pathology. No changes affecting motor and sensory neurones or glial cells have been demonstrated. Nothing in the nature of an inflammatory encephalitic reaction has been noted. Indeed, both from clinical observation and from analysis of this pathologic material, we have been unable to date to demonstrate any harmful effects of refrigeration upon the central nervous system.

Metastases.—A perusal of the several tables reveals at a glance how far advanced the cases of malignancy in this series have been, for the percentage involvement, with the exception of the lungs, is considerably higher in each organ system than the figures given by most authors. Such a study further confirms the rather characteristic distribution of metastases in the various forms of cancer which have been encountered, but adds little else, in this respect, to our previous knowledge. From the standpoint of the effect of refrigeration upon these metastatic foci, we are scarcely warranted in hazarding an opinion, based on the data available in this material. Since most of the patients died, the duration of life was so seldom more than a few weeks that one would scarcely expect to find any convincing evidence of regression. Furthermore, it is impossible to have a truly representative base line—biopsied tissues—from the metastatic areas. Thus, changes which are demonstrable at autopsy either grossly or microscopically are not necessarily indicative of regression, the result of refrigeration. Only time and a sufficient number of cases can establish factual evidence in this regard.

It is true that regressive changes are likely to be observed in the metastatic tissues from the refrigerated group. It is equally true that similar changes may be observed in any malignant tumor. Undoubtedly, it is almost impossible to exclude bias entirely in a matter where one's interest and enthusiasm are so closely bound up. Nonetheless, it is our impression that in the majority of those patients subjected to more than 120 hours of "hibernation," the regressive cell changes seem to be more marked, and to occur with greater regularity in persons subjected to refrigeration than in those who were not. In no instance, however, has complete necrosis of any metastatic area been observed.

X-RAY STUDIES

The only possible way to evaluate accurately the gross regression of metastatic tumor is by means of serial x-ray studies where the size of the lesion can actually be measured at successive intervals. Through the splendid cooperation of the members of the Department of Radiology, especially Dr. W. E. Chamberlain, Dr. B. R. Young, and Dr. R. K. Arbuckle, such studies were undertaken whenever possible as a routine control yardstick for the

clinical and pathologic findings. Initial roentgenograms were obtained in 33 of the experimental group. In 14 of these no subsequent studies were obtained, in most cases because of the death of the patient before such repeat pictures were indicated. Of the 19 remaining patients, 9 must be eliminated because their treatment was by local cold application only. Of the remaining 10, three had less than 50 hours of refrigeration, and four others had from 50 to 150 hours; only three received over 150 hours of generalized refrigeration. No change was noted by x-ray in the group having less than 50 hours of refrigeration, nor in three who were in the second group (the 50 to 150 hour series); no apparent change was observed in one of the three (a case of breast cancer [E. B.] with widespread skeletal metastasis) who had as much as 230 hours of hibernation.

The other three cases perhaps merit individual comment. Case 15 (E. G.) was a patient with advanced breast cancer who received local treatment for several months, and then, in the terminal stages of her disease, was the first patient ever to undergo "hibernation." All that can be said is that during the last three months of her life there was no increase in the size of any of the skeletal metastases which in general had been progressive in character over the preceding six-month period.

Case 47 (A. W.) was a patient with carcinoma of the thyroid with widespread generalized and skeletal metastases, who was maintained under observation for about ten months. Most of his treatment was of the local type, but he did receive about 120 hours of generalized refrigeration. Following a three-month treatment period, the x-ray examination revealed definite improvement of many of the lesions, and the discovery of no new areas. Five months later improvement was still noted in the lesions in the cervical spine, the ribs and clavicle, but there was evidence of increased destruction in the pelvic bones.

Case 96 (L. Q.) was a patient who had the fulminating type of acute lymphatic leucemia that occurs in a child. He received no x-ray treatment other than that unavoidably required for repeated pictures. Over a two-month period he had several brief periods of refrigeration, following each of which there was a temporary measurable decrease in the mediastinal area of involvement, as well as of the spleen, accompanied by a profound drop in the white blood cell count. These regressive changes, however, were transitory and incomplete. Positive tissue cultures were obtained from cervical nodes at autopsy in spite of what grossly appeared to be complete liquefaction necrosis of the tissues.

Obviously, these data are totally inadequate with which to draw any conclusions in respect to the effects of generalized refrigeration upon metastatic tumor tissue. From such data as we do have it becomes apparent that no significant changes are likely to occur in much less than 240 hours of such low temperature application. Whether complete regression of such metastatic foci would ever result is extremely unlikely, but it does not seem unreasonable to feel that generalized hypothermy might well be an important adjunct to other forms of therapy. Its further exploration is urged.

SUMMARY

1. The histopathologic findings of 50 patients with malignant disease subjected to local, generalized, or combined refrigeration are compared to those of 37 closely analogous terminal cases of malignancy given only the usual supportive treatment during the terminal stages.

2. Critical analysis of the heart, lung, liver, spleen, and kidney findings reveals no very significant differences in the two groups.

3. The occurrence of acute pancreatic changes, either gross or microscopic, in about 10 per cent of the persons given refrigeration is particularly discussed from the standpoints of etiology and prevention.

4. The effect of réfrigération upon metastatic disease, as demonstrated by serial x-ray as well as autopsy studies, is discussed. It is suggested that at least 240 hours of such generalized refrigeration is apparently needed to induce any significant regression of such metastases, and that such regressions are of irregular occurrence only.

5. The further exploration of the use of reduced temperature as an adjunct to other forms of treatment of cancer is urged.

Acknowledgment should be made to a very considerable number of the hospital staff for their respective contributions in the conduct of these studies, but especially to Dr. Temple Fay and Dr. Augustus McCravey for their clinical observations; and to the members of the Pathology Department, Dr. E. E. Aegerter, Dr. H. C. Lennon, Dr. A. R. Peale, and Dr. L. L. Lawry, for their help in the performance of the autopsies. Dr. C. L. Brown as internist, Dr. W. E. Burnett as surgeon, Dr. H. Roesler as cardiologist, and Dr. G. C. Henny as physicist, likewise are particularly deserving of our gratitude.

CLINICAL AND EXPERIMENTAL

THE DEVELOPMENT OF EOSINOPHILIA FOLLOWING LIVER THERAPY*

ROBIN N. ALLIN, M.D., AND OVID O. MEYER, M.D.
MADISON, WIS.

INTRODUCTION

SINCE the institution of liver in the treatment of pernicious anemia, it has been a well-known fact that eosinophilia sometimes develops following the administration of large amounts of raw or cooked whole liver. That eosinophilia may follow the oral administration of liver extract has remained a debated issue. A review of the literature has revealed no reference to the development of eosinophilia following the administration of parenteral liver extract.

In 1927 Watkins and Berglund⁴ reported the development of a progressively rising eosinophilia in a patient with pernicious anemia. This patient had been placed on a raw liver diet. Up to the eighteenth day of observation the percentage of eosinophiles had remained relatively constant, but from that date on, frequent differential counts through the fiftieth day revealed a progressive eosinophilia to about 48 per cent. Whitby⁶ in 1928 reported the development of eosinophilia in four cases of pernicious anemia following the institution of liver therapy. Two patients had received raw liver only. One patient had received a combination of raw and cooked liver, and one had received cooked liver only. Eight to eleven weeks after institution of therapy a rise in eosinophiles to 6 to 8 per cent was noted. In one patient receiving raw liver alone a maximum of 26 per cent eosinophiles was attained. Smith and Whitby³ reported the occurrence of eosinophilia in patients convalescing from various medical and surgical conditions after they had received a diet of cooked liver over a period of from six to forty days. A maximum rise to 61 per cent was noted in one instance, but this was in a patient with Hodgkin's disease. Meulengracht and Holm¹ concluded that eosinophilia in the liver treatment of pernicious anemia appeared in a marked and persistent form when treatment was carried out with large doses of raw calves' liver and that this eosinophilia persisted as long as raw liver was given. The increase in eosinophiles in these cases ranged from 20 to 40 per cent, and in one case was as high as 74 per cent. Control patients suffering from various other diseases responded in a like manner. This eosinophilia was usually absent when fried liver or liver extract was employed. Whitby and Britton⁵ hold to the view that eosinophilia occurs only with the administration of raw liver and not with liver extract. Murphy²

states that in patients ingesting either whole liver or liver extract there may occur an increase in the number of eosinophiles, in some cases to rather high levels. He reports one patient who received whole liver and in whom there developed an eosinophilia of 50 per cent of a total of 18,000 leucocytes. When this patient was given liver extract by mouth, there was some decrease, but not until the extract was given intramuscularly were normal values established.

REVIEW OF CASES OF PERNICIOUS ANEMIA SEEN IN THE STATE OF WISCONSIN GENERAL HOSPITAL

Since a review of the literature revealed few references to the development of eosinophilia following whole liver ingestion, no references to eosinophilia following parenteral liver therapy, and conflicting views regarding the development of eosinophilia following oral liver extract, it was felt that a study of the cases of pernicious anemia seen in the State of Wisconsin General Hospital from September, 1925, through September, 1938, might be instructive. This review was undertaken for the purpose of determining what form or forms of liver therapy produced eosinophilia, and to what extent.

TABLE I

ANALYSIS OF PERNICIOUS ANEMIA PATIENTS SEEN IN THE STATE OF WISCONSIN GENERAL HOSPITAL SEPTEMBER, 1925, THROUGH SEPTEMBER, 1938

TYPE OF THERAPY	TOTAL CASES	NUMBER WITH EOSINO-PHILIA	PER CENT OF TOTAL WITH EOSINO-PHILIA	PER CENT AVERAGE MAXIMUM EOSINO-PHILIA	REMARKS
No specific treatment	45	24	53.3	5.9	Eosinophilia of unknown cause
Whole blood transfusions	9	2	22.2	20.8	Individual maximum eosinophilia 34.6% and 7.0%
Whole blood (intramuscular injections—5 c.c. twice a week)	1	1	100	30.0	Maximum eosinophilia obtained after 2 months
Whole cooked liver	13	10	76.9	8.6	
Extralín (Lilly)	1	1	100	8.0	
Cofron (Abbott)	1	1	100	10.0	
Oral liver extract No. 428—Lilly	2	0	0	0	
Oral liver extract No. 29—Valentine	7	3	42.8	6.0	
Oral liver extract No. 343—Lilly	30	5	16.6	6.8	
Mixed liver therapy	91	31	34.1	10.4	Various forms of oral and parenteral liver, individual maximum eosinophilia 50.0%
Intramuscular liver extract—Lilly	79	36	45.5	11.3	Individual maximum eosinophilia 45.0%
Total cases	279				
Total number of cases receiving liver					224
Total number of cases with eosinophilia after liver therapy (excluding 6 cases with allergic background)					87 (38.8%)

For the purpose of this study, as well as for the experimental work to be reported in this article, a percentage of eosinophiles in excess of four was considered abnormal.

A total of 279 cases of pernicious anemia was studied. Of these, 224 received some form or forms of liver therapy, and of this latter group 87 showed an eosinophilia at some time. The results are summarized in Table I.

As frequent differential counts were not routine, it was impossible to determine: (1) the interval between institution of liver therapy and the beginning of eosinophilia, and (2) whether or not there occurred a gradual progressive eosinophilia throughout the period of liver treatment or merely a sporadic increase in eosinophiles.

EXPERIMENTAL STUDIES

An effort was made to study more closely the eosinophilic response to various forms of liver treatment in well or nearly well individuals, and to compare this response to that seen in patients with pernicious anemia who had received no liver therapy and from whom no allergic history could be obtained.

METHODS

In studying the four control cases, seven different "regimens" were employed. Two patients received 0.5 c.c. of Lilly's reticulogen intramuscularly every other day for a total of seven injections. Two patients received 3.0 c.c. of Lilly's liver extract intramuscularly every other day for seven injections. Three patients received one-half pound of cooked whole beef liver daily for a period of fourteen days.

The patients with pernicious anemia were treated according to the regular schedule for uncomplicated pernicious anemia. They received 3.0 c.c. of Lilly's extract intramuscularly every fifth day throughout the entire period of their hospitalization.

All patients were followed for at least one month. Total leucocyte counts were made in duplicate. The percentage of eosinophiles was determined each time by counting a total of 400 cells on three cover slip smears stained by Kingsley's method. In all persons with pernicious anemia and in some of the controls counts were made daily. In no instance were counts made less than three times each week, and they were always made at approximately the same time of day (2 P.M.).

In an effort to establish or rule out any correlation between skin reactions to liver extract and pathologic increases of eosinophiles following liver therapy, skin tests were done in most experiments before institution of treatment and again at the end of one month of therapy. For these skin tests 0.05 c.c. of Lilly's liver extract was injected intracutaneously. Experience revealed that the maximum reaction occurred after five minutes. It was arbitrarily decided that any reaction showing pseudopods should be taken as positive. The appearance of wheals per se was not considered representative of a positive reaction, since fourteen of fifteen normal tested individuals developed wheals.

RESULTS

An analysis of the control and anemic cases, with a brief résumé of each, follows:

A. Controls.—CASE 1. White male, 32 years old (95023). Diagnosis: delayed union of fractured tibia. The patient was seen in the hospital on five previous admissions when 16 total and differential white blood cell counts were made, and only once was an elevation of

eosinophile count above normal noted, and that to 5 per cent. The initial skin test revealed a wheal approximately 25 mm. in diameter without pseudopods. Lilly's liver extract regimen was then instituted after an initial blood count (see Chart 1). Fifteen days after the beginning of treatment an eosinophilia of 4.25 per cent was noted. A maximum response of 7.75 per cent was attained on the twenty-first day. The skin test at the end of the first month remained essentially unchanged with no pseudopods. After a rest period of ten days the patient received whole cooked liver irregularly for one week, followed by a period of two weeks during which he was given one-half pound of whole cooked liver daily. On the thirtieth day following the institution of the whole cooked liver regimen, a maximum eosinophilia of 7.25 per cent was attained. As shown in Chart 1, a progressive eosinophilia did not occur following either regimen, and with the intramuscular extract eosinophilia did not develop until after liver therapy had been stopped.

Chart 1.—The curves represent the leucocyte response in a normal individual during treatment with (1) liver extract intramuscularly, 3 c.c. every other day for seven doses; (2) whole cooked liver, one-half pound daily for a period of fourteen days.

CASE 2. White male, aged 22 years (9715). Diagnosis: healed lupus vulgaris (in for plastic repair). The initial skin test revealed no reaction whatsoever. The patient received Lilly's liver extract and later cooked liver, but at no time did the eosinophiles exceed normal limits.

CASE 3. White male, 29 years old (202906). Diagnosis: supracondylar fracture left femur, uncomplicated. The initial skin test revealed a wheal 10 mm. in diameter with no pseudopods. Observation for a period of one month following institution of reticulogen therapy revealed no eosinophilia.

CASE 4. White male, 49 years old (87237). Diagnosis: non-union fracture of left tibia. The initial skin test revealed a wheal 12 mm. in diameter without pseudopods. The patient received reticulogen and subsequently cooked liver. With each of these the eosinophile count reached a maximum of 5 per cent on two occasions. These increases were not considered to be significant.

Analysis of Control Cases.—Of the four control patients only one, Case 1, showed a definite eosinophilia and that was of approximately the same degree following cooked liver and intramuscular liver extract. Skin tests before and after the first regimen were considered to be negative. Skin tests on the remaining three controls were also negative and in none of these did an eosinophilia develop.

B. Pernicious Anemia.—CASE 1. White male, 38 years old (107597). The initial skin test revealed a wheal 17 by 17 by 2 mm. with no pseudopods. The patient did not develop eosinophilia during the month's observation when he received 3 c.c. of Lilly's liver extract intramuscularly every five days.

CASE 2. White male, aged 65 years (206698). The initial skin test revealed a wheal 15 by 16 by 2 mm. with two pseudopods about 2 mm. in length. Only one differential leucocyte count was obtained before institution of therapy. The patient developed a slight eosinophilia on the sixth day of parenteral liver extract therapy, but this was irregularly present thereafter with a maximum eosinophilia of 5.75 per cent on the thirteenth day. This level was not considered to be significant. A skin test at the conclusion of the experiment was not obtained.

Chart 2.—The curves represent the leucocyte response in a patient with pernicious anemia, previously untreated, while receiving 3 c.c. of liver extract intramuscularly every fifth day.

CASE 3. White female, 50 years old (27360C). The initial skin test showed a wheal 20 by 15 by 2 mm. with three pseudopods, two of which were 10 mm. in length and 2 mm. in width. The third pseudopod was 2 mm. in length. Only one differential count was obtained before parenteral liver therapy was started. Chart 2 depicts the development of the progressive eosinophilia beginning on the eighteenth day and attaining a maximum of 9.75 per cent on the twenty-eighth day. Although liver therapy was continued, the subsequent level of eosinophilia through the thirty-ninth day, the last day of observation, varied between 6.75 and 8.25 per cent.

CASE 4. White female, 60 years old (207666). The initial skin test showed a wheal 14 by 18 mm. with no pseudopods. The patient exceeded the normal percentage of eosinophils only twice during the month's observation, when she developed a maximum eosinophilia of 5.5 per cent. The skin test at the end of the period of observation revealed a wheal 14 by 13 by 1 mm. with two pseudopods, 2 by 1 mm. and 17 by 2 mm. That a profound eosinophilia would have developed with further observation can only be surmised.

CASE 5. White male, 72 years old (105381). The initial skin test revealed a wheal 14 mm. in diameter with one pseudopod 5 mm. in length. The patient's blood showed a normal eosinophile count throughout the period of observation. A final skin test revealed a wheal 12 by 15 by 0.5 mm. with no pseudopods.

Analysis of Cases With Pernicious Anemia.—Of the five patients with pernicious anemia only one, Case 3, developed a definite eosinophilia. Cases 2 and 3 had positive initial skin tests. Case 1 had a negative initial skin test and developed no eosinophilia. Case 4 had a negative initial skin test and developed no significant eosinophilia but had a positive terminal skin test. Case 5 had a positive initial skin test, developed no eosinophilia, and had a negative terminal skin test.

DISCUSSION

A review of the records of patients with pernicious anemia seen in the State of Wisconsin General Hospital revealed the development of an average maximum eosinophilia varying from 6 to 11.25 per cent in 87 of the 224 persons who had received various forms of liver, and in whom other causes of eosinophilia were eliminated. However, 24, or 53.3 per cent, of the 45 patients who had received no specific treatment and in whom no allergic basis could be discovered showed an eosinophilia, although the average maximum rise was to 5.9 per cent only. No persons in this series received raw liver alone. Of the persons treated with whole cooked liver, 76.9 per cent developed eosinophilia. This incidence of cases developing eosinophilia was higher than that for any group receiving other types of liver therapy. The lowest frequency of eosinophilia coincident with liver treatment was that following oral extract (Lilly's No. 343), being only 16.6 per cent. The instances given in Table I, where only one or two cases received a specific type of treatment, are not considered. Importantly, this review showed that 45.5 per cent of the patients who received intramuscular liver extract developed eosinophilia with an average maximum rise to 11.25 per cent. The degree of eosinophilia in this group surpassed that of any other receiving liver therapy.

It follows, therefore, that eosinophilia may occur in patients with pernicious anemia who have received no specific treatment and in whom there is no obvious allergic or parasitic basis (stool examinations for intestinal parasites were done routinely on all cases of pernicious anemia); that eosinophilia may develop following cooked liver and orally and parenterally administered liver extracts, but apparently more frequently following the former. In no type of therapy, however, is this eosinophilia a regular occurrence.

Although definite deductions could not be made from this small experimental series, the results tend to show that eosinophilia may follow intramuscular liver extract therapy. Further, it is borne out, in agreement with the previously held view,^{1, 3} that eosinophilia following liver therapy is not a response peculiar to pernicious anemia. No correlation could be found to exist between skin tests with liver extract and the development of eosinophilia in the peripheral blood. This, of course, does not prove that the eosinophilia is not an allergic phenomenon but rather that skin tests with liver extract, as with many food extracts, may be unreliable. The experimental cases show that eosinophilia may develop after liver therapy has been stopped.

SUMMARY

1. Of the 279 patients with pernicious anemia seen in the State of Wisconsin General Hospital from September, 1925, through September, 1938, 224 received one or more forms of liver therapeutically. Allergic states and parasitic infestation had been excluded in each instance. Of this group of 224 cases, 87 developed eosinophilia at some time or other. However, eosinophilia of lesser degree was found in 24 of 45 cases in whom no evidence of allergy could be found and who had received no form of liver up to the time eosinophilia was discovered. Results of this review are analyzed in Table I.

2. Four control patients, who had no systemic disease and from whom no allergic history could be obtained, were observed for periods of one month following institution of liver therapy. Only one developed an eosinophilia.

3. Five previously untreated patients with pernicious anemia were similarly observed. One person developed definite eosinophilia while receiving parenteral liver extract.

4. An attempt to correlate a local dermal reaction to liver extract and the development of eosinophilia was unsuccessful.

CONCLUSIONS

The feeding of whole liver and the administration of oral and parenteral liver extracts may be followed by the development of eosinophilia in patients with pernicious anemia as revealed by the analysis of the records of such patients seen in the State of Wisconsin General Hospital.

Experimental studies revealed that: (1) Eosinophilia may follow the administration of whole liver and parenteral liver extract in presumably normal individuals; (2) eosinophilia may occur in patients with pernicious anemia following the parenteral administration of liver extract; (3) eosinophilia so induced may persist after cessation of liver therapy.

It has not been demonstrated that the eosinophilia, sometimes found following the administration of liver, is an allergic response nor has this possibility been excluded. Further investigation will be necessary to establish the cause for eosinophilia resulting from liver therapy.

PRECIPITIN REACTIONS IN RHEUMATOID ARTHRITIS

J. GRAHAM BRUCE, M.D., AND MARGARET CASWELL, A.B.
SPRINGFIELD, MASS.

SINCE the clinical course and pathologic findings of rheumatoid arthritis differ from osteo-arthritis, it is reasonable to presume that they also have separate etiologic factors. In the etiology of rheumatoid arthritis, the contributing factors are many, such as environment, heredity, avitaminosis, faulty metabolism, infection, and psychic trauma. Of all these factors, infection is believed to play a prominent role, and the *Streptococcus hemolyticus* is implicated in some way as suggested by the agglutination reaction.¹ The infection hypothesis is bolstered also by the fact that rheumatoid cases show an elevated sedimentation rate, a rise in serum globulin and a lowering of serum albumin, an elevated filament-nonfilament count, and a positive agglutination and precipitin reaction to *Streptococcus hemolyticus*.²

In this study we are presenting a series of cases of arthritis in which streptococcus precipitin reactions were done. Comparable agglutination reactions have been done by numerous investigators. Nicholls and Stainsby³ in 1931, using a "typical strain" of *Streptococcus hemolyticus*, obtained a positive agglutination in "practically all cases." In the following year Clawson and Weatherby,⁴ and Dawson, Olmstead, and Boots,⁵ found that 59 and 67 per cent, respectively, of rheumatoid types presented a positive agglutination. Wainwright⁶ in 1934 observed that the blood sera of 90 per cent of 87 cases of rheumatoid arthritis were positive. He used both living and heat-killed antigens. Nearly all these men used a "typical strain" of *Streptococcus hemolyticus*.

METHOD

Using the hydrochloric acid extract as antigen, Neil and Hartung⁷ in 1937 showed the precipitin reaction to be comparable to the agglutination reaction, in which live bacteria were used. We, therefore, used the hydrochloric acid extract as antigen because of the difficulty in keeping a growth of streptococcus alive. The method of obtaining the extract from a culture of *Streptococcus hemolyticus*, using the Lauecfield method, Porge modification, is as follows: a liter of plain broth having pH 7.6 is inoculated with 6 c.c. of fresh growing broth culture of *Streptococcus hemolyticus* and incubated at 37° C. for eighteen hours. The broth culture is then centrifuged and the precipitate is suspended in 0.85 per cent sodium chloride. Normal hydrochloric acid is added to give a resulting concentration of twentieth-normal. This acidified suspension (volume approximately 15 c.c.) is immersed in boiling water for fifteen minutes, then cooled to room temperature and centrifuged for thirty minutes. The resulting

supernatant is neutralized with sodium hydroxide, and the precipitate is discarded after centrifuging. The crystal-clear, slightly yellowish supernatant is the crude antigen and is ready for use.

The type-specific fraction designated as "M" may be obtained from this crude antigen by a series of extractions, using ethyl alcohol and sodium acetate. However, since Neil and Hartung⁷ in their study demonstrated that the crude antigen gave as many positive precipitin tests as the refined alcoholic extract containing the type-specific "M" fraction, and less than 0.1 per cent carbohydrate, only the crude antigen was used in this series. Three different antigens were used in the course of these precipitin reactions. The organism used in all three antigen preparations was a *Streptococcus hemolyticus*, beta type, freshly isolated from pathogenic sources.

32	E. Ois	F	28	4 years	000	Rheumatoid	

RESULTS

In 32 cases of the rheumatoid or mixed type there were 22, or 68.7 per cent, whose sera gave positive precipitin reactions. These results compare favorably with those of other workers, mentioned previously in this report. The 13 cases of osteo-arthritis, with but a few exceptions, gave negative results. The normal controls were also all negative.

Thus, it would seem that in the light of our present knowledge concerning arthritis, the *Streptococcus hemolyticus* is in some way implicated. Arthritis has been produced experimentally in rabbits by injecting small amounts (0.1 to 2 c.c.) of a broth culture of *Streptococcus hemolyticus* intravenously. The sedimentation rates, as well as the streptococcus agglutinins, were increased in these animals, whether they developed arthritis or not.⁸ These observations tend to make one suspect the streptococcus as an etiologic factor, except that the pathology produced in the joints clears up in a short time.

However, it is more likely that the agglutination test is nonspecific. The reaction is highly characteristic for atrophic arthritis, and Hench says "does not bar the conclusion that the agglutinins present in these sera are the result of rheumatoid disease."⁹ The Wassermann reaction is nonspecific in the sense that it is not a specific test for the presence of the spirochete. By the same token the agglutination and the precipitin reactions may be specific for atrophic arthritis, but without etiologic significance.

Other workers¹⁰ have shown that the agglutination titer may change from month to month on the same patient without any change in the sedimentation rate or clinical course of the disease. These men feel that the sedimentation rate is better as a diagnostic test than the agglutination reaction.

The ubiquitous streptococcus can be implicated; this is about all that can be said. Most authors agree with this postulate. More work to uncover the exact etiology of rheumatoid arthritis will have to be done before the exact role which the streptococcus plays can be determined. For the present, we may only say that the precipitins, as well as the agglutinins, in the sera of patients with rheumatoid arthritis are indirect evidence that infection plays a role in the etiology of this disease.

CONCLUSIONS

1. In a series of 32 cases of rheumatoid arthritis, the sera of 22 showed precipitins to the *Streptococcus hemolyticus* in high titer.
2. Four out of 15 cases of osteo-arthritis had a positive precipitin reaction, and none of the normal controls were positive.
3. The precipitin and agglutination reactions to the *Streptococcus hemolyticus* are indirect evidence that the streptococcus plays a part in rheumatoid arthritis.

LEUCOCYTE CHANGES IN ACUTE PERITONEAL IRRITATION*

ROBERT E. KAUFMAN, M.D., AND FREDERICK VOM SAAL, M.D.
NEW YORK, N. Y.

SINCE the introduction of the Schilling count¹ into clinical hematology, there has been much interest in the so-called "shift to the left." This is a term used to indicate an increased percentage of immature polymorphonuclear leucocytes in the differential count. The adult polymorphonuclear cells have two or more distinct lobes, connected by a very fine, threadlike filament. Any polymorphonuclear cell without this definite filament is not adult, even if there are two or more lobes. There are many different terms used to contrast these two types of cells, such as mature and immature; adult and young; segmented and nonsegmented; segmenters and band forms; filamented and nonfilamented; segmented and juvenile plus stab or staff cells. It is now customary to group together the juvenile and stab cells of Schilling's classification, and to call all polymorphonuclear cells either mature or immature.^{2, 3}

There is considerable difference of opinion concerning the normal percentage of immature polymorphonuclear leucocytes in the capillary blood. Some^{1, 4, 5} feel that normally there are only 3 to 6 per cent of these cells compared to the total number of white cells; and that anything above 5 per cent should be considered a shift to the left. Most of the more recent observers, however, follow the teaching of other authorities^{2, 6-8} and find a normal of 5 to 10 per cent, with the upper limit at 10 to 12 per cent. We consider 4 to 12 per cent normal; 13 to 20 per cent a slight shift; 21 to 39 per cent a moderate shift; and 40 per cent and over a marked shift.

The percentage of immature polymorphonuclear leucocytes has considerable diagnostic and prognostic value.^{1, 3, 9, 10} It is often assumed that a shift to the left indicates only the presence of infection. However, a shift may also be found in rupture of a viscus, thrombosis (coronary and elsewhere), hemorrhage, pregnancy, malignant neoplasms, acute ileus,¹¹ bone marrow irritation, such as that due to metastatic infiltration, and following various types of acute peritoneal irritation.

Since 1933, when the Schilling differential count was introduced as a routine in this hospital, we have been impressed with the constancy of the left shift, often extremely marked, in cases of acute peritoneal irritation. This observation has at times aided considerably in diagnosis. We, therefore, think it of interest to report a series of 132 differential counts in a group of 104 patients with various kinds of acute peritoneal irritation, proved by operation or autopsy.

*From the Lenox Hill Hospital, New York.
Received for publication, November 16, 1939.

Several sources of error in our data must be recognized. The counts were made by 58 interns; hence the human error must be considered. In addition, there is a moderate statistical error inherent in counting only 100 to 200 cells.^{12, 13} As a result of these factors, the figures represent the usual conditions of medical practice in most hospitals.

"PRIMARY" PERITONITIS

The group of 9 cases of "primary" peritonitis is most illuminating in this connection. By primary peritonitis we mean "those cases which suddenly develop peritonitis unassociated with evidence of a pre-existing abdominal inflammation."¹⁴ Of the 9 counts (Table I), all except one (32 per cent) show a marked increase in immature polymorphonuclear leucocytes (44 to 74 per cent). The patient with only 5,750 white blood cells had the highest percentage of immature cells (74 per cent).

TABLE I
"PRIMARY" PERITONITIS

PERFORATED PEPTIC ULCER

Table II shows the counts of 24 cases of perforated peptic ulcer. It will be noted that the shift is not so constant in this group of cases as in the preceding. On the whole, however, there is a definite trend for a rather marked shift. One example will suffice to show how rapidly the immature cells may be poured into the peripheral blood after a perforation of an abdominal viscus.

A 38-year-old man was admitted to the hospital for a partial pyloric obstruction from a cicatrized ulcer. There was no suggestion of a perforation; his temperature and pulse were normal; his differential count showed 86 per cent polymorphonuclear cells, of which only 8 were immature. Twenty-four hours after admission the patient complained of sudden onset of terrific epigastric pain, and the diagnosis of perforated peptic ulcer was made clinically. Fifteen minutes after the onset of pain one of us did a differential count and found 92 per cent polymorphonuclear cells, of which 24 were immature. One and a half hours after the perforation, just before operation, the count was repeated by the same observer, and there were now 97 per cent polymorphonuclear cells, of which 39 were immature. Operation confirmed the diagnosis.

PERFORATION OR GANGRENE OF SMALL INTESTINE

We have recorded in Table III the results of 17 counts done on 6 patients with perforation or gangrene of the small intestine. These persons, including those with gangrene in whom a definite perforation could not be found, all had purulent peritoneal fluid containing organisms. The large number of counts

per person indicates the difficulty of arriving at a diagnosis in this type of case, and the consequent delay in operating. It is important to note that in the cases with a low total white blood cell count the shift to the left is usually most marked. The practical significance of this observation is evident, since it is in those cases with a low total white blood cell count that the surgeon tends to delay unnecessarily. An example will illustrate this point.

A 39-year-old German bartender was admitted to the hospital with a history of four days of dull, intermittent midabdominal pain, anorexia, nausea and frequent vomiting. For the past ten years he had had a right inguinal hernia, which had never given him any trouble.

On examination he was found to have marked congestion of the tonsils and pharynx, a few small axillary and epitrochlear nodes, and a right indirect inguinal hernia with a relaxed external ring, admitting one finger. His temperature was 101.2° F. and his pulse was 100 on admission, but both came down to normal within twelve hours and remained normal. The initial blood count showed 7,000 white blood cells; polymorphonuclear cells 79 per cent, of which 40 were immature; lymphocytes 21 per cent. The next day the total count was 10,000; polymorphonuclear cells 48 per cent, of which 30 were immature; lymphocytes 42 per cent; monocytes 6 per cent; eosinophiles 4 per cent. The following day the total white blood cell count was not determined, but the differential count showed polymorphonuclear cells 57 per cent, of which 40 were immature; myelocytes 4 per cent; lymphocytes 24 per cent; monocytes 11 per cent; eosinophiles 4 per cent. During the first four days in the hospital he had no symptoms, but on the fifth day he developed pain in the right inguinal region. The external ring was found filled with intestines. Shortly thereafter the patient reduced the hernia himself. Operation was nevertheless advised, but was not considered urgent. The patient insisted on going home, for he felt well and wished to return to work. The next afternoon he returned in shock, after having vomited all night. He died two hours after readmission. Autopsy revealed two areas of gangrene, 6 cm. apart, in the distal ileum, one recent and the other old.

PERFORATED APPENDIX

The cases of perforated appendix, either without abscess or with an abscess of less than five days' duration, are listed in Table IV. In this group also there is a tendency for those cases with a low total white blood cell count to have a more marked shift than those with a higher count.

To show how rapidly and dramatically the blood picture can change, we wish to mention the case of a 2-year-old female child who was admitted to the hospital with symptoms and signs suggesting an acute abdominal inflammation. The initial count, made forty-eight hours after the onset of symptoms, was as follows: white blood cells 7,800; polymorphonuclear cells 62 per cent, of which but 22 were immature; lymphocytes 38 per cent. This relatively normal count was in part responsible for a short delay in asking the surgeons to see the child. Five hours later the count was white blood cells 4,000; polymorphonuclear cells 80 per cent, of which 70 were immature; lymphocytes 20 per cent. Operation was performed immediately after this count, and a perforated appendix was found.

PERFORATION OF SIGMOID DIVERTICULI

In Table V we have recorded the results of 6 counts in 4 cases of perforation of sigmoid diverticuli. All the counts, with one exception, show a marked shift to the left. Here again the low total counts were accompanied by a high immature count, even when the polymorphonuclear cells were not markedly increased. The one case in which no significant shift was recorded had a total white blood cell count of 33,800 and a polymorphonuclear cell count of 93 per cent.

PERFORATED GALL BLADDER

It is well recognized by clinicians that the severity of most cases of acute cholecystitis is extremely difficult to evaluate, and that an empyema or perforation of the gall bladder may be present with very slight symptoms and signs or changes in the blood picture.¹⁵⁻¹⁷ In our small series of 6 proved cases of perforated gall bladder only 1 out of a total of 9 counts showed a greater percentage of immature cells than 32 (Table VI). It is unfortunate, but apparently true, that the degree of shift cannot be counted on as an aid in diagnosing the severity of a cholecystitis.

HEMORRHAGIC PANCREATITIS

The cases of acute hemorrhagic pancreatitis in our series (Table VI) are too few to be discussed in detail. There is a tendency for an extremely high polymorphonuclear cell percentage and for a marked shift to the left, although the latter is not consistently noted. In typical instances of this disease, the aid which may be had from the blood count is unnecessary, as the clinical picture of

a surgical abdominal emergency is so striking. If one must attempt to distinguish between hemorrhagic pancreatitis and coronary occlusion, as occasionally happens, it would appear that a very high polymorphonuclear count and a marked shift, especially if they occur within a few hours after the onset of symptoms, favor the former diagnosis.

RUPTURED ECTOPIC PREGNANCY, GRAAFIAN FOLLICLE, CORPUS LUTEUM CYST

A sudden and profuse hemorrhage into the peritoneal cavity may give rise to a marked shift to the left, similar to an infectious process; but usually if the hemorrhage is not large or sudden, the shift is not noteworthy. Three cases of ruptured ectopic gestation and seven cases of rupture of a Graafian follicle or

of a corpus luteum cyst are recorded in Table VII. The presence of a marked shift in a patient suspected of having had a rupture of an ectopic pregnancy is of considerable aid in deciding on an immediate operation. On the other hand, it is reassuring to note the low immature counts of the cases of rupture of a Graafian follicle or corpus luteum cyst, as these conditions do not require operation.

One patient who was known to be about two months pregnant had a white blood cell count of 9,850, with 86 per cent polymorphonuclear cells and 65 immature cells six hours after the onset of vague abdominal complaints. As the symptoms and signs were mild and as they rapidly subsided, she was allowed to go home. She returned thirteen days later, was immediately operated upon for a ruptured ectopic pregnancy, and died within a few days from uremia. If the extremely marked shift found on admission, and undoubtedly due to a sudden profuse intra-abdominal hemorrhage, had received due weight, this patient's life might well have been saved.

MISCELLANEOUS CASES OF ACUTE PERITONEAL IRRITATION

Various types of acute peritoneal irritation are gathered together in Table VIII, and it will be seen that the one thing these cases have in common is a sudden peritoneal insult. Most of them show the typical marked shift, which, when present with abdominal symptoms, is very important diagnostically. One case will well illustrate the value of understanding the significance of a high immature count in an acute abdominal condition.

A 61-year-old female had been on the medical ward for ten weeks with hypertensive cardiovascular renal disease. She had been decompensated on admission, but was doing very well when she was awakened one morning by rather severe generalized abdominal pain. She vomited several times, perspired profusely, and had cold extremities. Examination soon after the onset of symptoms revealed diffuse abdominal tenderness, especially in the left upper quadrant. Her temperature was 98.0° F.; her pulse was 70; and her respirations were 24 per minute. We were under the impression that we were dealing with an acute abdominal condition of some sort. A blood count, performed shortly after the examination or five hours after the onset of the pain, was as follows: white blood cells 8,600; polymorphonuclear cells 95 per cent, of which 83 were immature. Because of the extreme shift to the left, a diagnosis of acute peritonitis seemed almost certain. For this reason, an abdominal tap was immediately performed and 1 c.c. of turbid, straw-colored fluid with numerous flecks of fibrin was removed. A smear showed a variety of gram-positive and gram-negative bacilli and cocci, later substantiated by culture. The organisms obviously entered the abdominal cavity from the intestinal tract, probably as the result of a leak through the chronically distended gut or following a mesenteric thrombosis. Because of the patient's poor cardiovascular condition, operation was deemed inadvisable, and strangely enough, the patient made an uneventful recovery in a few days and subsequently went home.

DISCUSSION

We wish to emphasize that in the presence of suspected abdominal pathology, a high percentage (over 35 to 40 per cent) of immature polymorphonuclear leucocytes in the peripheral blood suggests acute peritoneal inflammation, almost always requiring immediate surgical intervention. In Table IX the immature cell percentages of all the counts are averaged according to the number of hours elapsing from the onset of symptoms to the time the count was done. This grouping brings out the fact that in this series the average immature count is almost identical in the group in which the counts were done shortly (less than ten hours) after the onset of symptoms and in the group in which many hours or even days elapsed. It is, therefore, apparent that the shift does not depend so much on infection as on sudden peritoneal shock or irritation. Even a very few hours after the perforation of a gastric ulcer, for example, there is usually noted a considerable shift. This is evidently not dependent on an infection, but is probably due to an inflammation of a chemical nature.

TABLE IX

ONSET OF SYMPTOMS TO TIME OF COUNT	AVERAGE PER CENT IMMATURE POLYS.
Under 10 hours	34.0
11-30 hours	33.3
Over 30 hours	34.3

TABLE X

TOTAL W.B.C.	AVERAGE PER CENT IMMATURE POLYS.
Under 10,000	41.2
10,000-20,000	30.2
20,000-30,000	34.7
Over 30,000	30.3

While one should consider the blood count as a whole, our experience with this series of patients makes us feel strongly—as do many others^{1, 2, 3}—that the degree of shift is the most important aspect of the hematologic picture in acute abdominal conditions, with the exception of gall bladder pathology. It must be realized, however, that a slight or absent shift does not by any means rule out shock or severe intra-abdominal disease. It is of the utmost importance to recognize the significance of a high percentage of immature polymorphonuclear leucocytes in the presence of a low total white blood cell count. It will be seen from Table X that the greatest shift on the average was in those cases in which the total white blood cell count was “normal,” i.e., under 10,000. It is often in the patients with normal total white blood cell counts that delay in operation seems safe to the surgeon, whereas less attention to the total and more attention to the degree of shift would aid considerably in diagnosis and prognosis.

CONCLUSIONS

1. A marked shift to the left in the differential blood smear is frequently present in all types of acute peritoneal irritation, even without infection.
2. The absence of a marked shift does not eliminate the possibility of acute peritoneal irritation.

3. In the presence of a low total white blood cell count, a definite shift is of especial importance in diagnosis and prognosis.

4. Repeated differential smears, properly interpreted, aid materially in deciding when and whether to operate for a suspected surgical abdominal emergency.

We wish to express our sincere thanks and appreciation to Dr. Henry Henstell for considerable aid in the preparation of the manuscript. Also to Miss Victoria Braun and her staff of the record room for their cheerful cooperation.

THE EFFECT OF BELLADONNA ON THE APPETITE OF PATIENTS WITH OBESITY AND WITH OTHER DISEASES*

JAMES A. GREENE, M.D., IOWA CITY, IOWA

IT WAS noted in a previous report¹ that relative inactivity was an important factor in the production of excess body weight in a majority of obese patients. These findings indicate that the appetite was not reduced in proportion to the activity. That there is a disturbance in control of appetite in such patients is supported by the additional fact that many patients state that hunger prevents them from adhering to a low calorie diet. Our interest in the control of hunger by medication was aroused several years ago when a patient stated repeatedly that she was able to follow a low calorie diet only so long as she took a medication which contained belladonna and bromide. This observation caused us to prescribe tincture of belladonna alone, or in combination with bromide or with phenobarbital, to other patients without their knowledge of the purpose.

TABLE I

DIAGNOSIS	TINCTURE BELLA- DONNA AND BROMIDES		TINCTURE BELLADONNA		TINCTURE BELLA- DONNA AND PHENOBARBITAL		TOTAL
	APPETITE		APPETITE		APPETITE		
	DECREASED	NOT AFFECTED	DECREASED	NOT AFFECTED	DECREASED	NOT AFFECTED	
Obesity	24	3	3		7	2	39
Diabetes and obesity			1		2		3
Diabetes			1		1		2
Chronic pyelo- nephritis			1				1
Total	24	3	6	0	10	2	45

It is to be noted from Table I that the appetite was diminished in 40 of 45 patients following the administration of such medication. These results, we believe, are higher than would be obtained in a larger series of cases. That the medication was an important factor in reduction of appetite is shown by the fact that ten patients who omitted the medication of their own accord resumed it because they noted that hunger returned. The duration of the effect has varied from as short as three weeks to as long as two years. The duration of the effect in most patients appears to continue indefinitely as long as the medication is continued. One patient with diabetes and moderate obesity was of particular interest. She had never been able to control the diabetes because

*From the Department of Internal Medicine, State University of Iowa, College of Medicine, Iowa City.

Received for publication, November 17, 1939.

hunger caused her to eat between meals. The administration of tincture of belladonna, 10 drops three times daily, before meals, eliminated this hunger and permitted her to control the diabetes.

Another patient presented an unusual case. She was forced to limit her activity because of chronic pyelonephritis and hypertension. She began to gain weight following this diminished activity. The administration of tincture of belladonna decreased her food intake sufficiently to stop the gain in body weight. Omission of the drug at a later date was followed by gain in body weight and a constant body weight again followed the administration of the drug. The prescribed diet was not altered during these periods of observations, and she voluntarily stated that her appetite was diminished during the periods of medication.

The cause of the increase in appetite in patients with obesity is not known. Harrington² and Newburgh³ concluded from their studies that many patients ingested food at frequent intervals because of nervousness or of habit. Our observations support this contention in certain patients, and it is for this reason that a mild sedative is of distinct aid in controlling the appetite in such patients. We have had only three patients who were given phenobarbital alone. The appetite was not altered in two, but it was definitely decreased in the third.

The fact that belladonna decreased the appetite in certain patients suggested that an alteration of motility of the stomach or small intestine may be a contributing cause. A series of investigations regarding this point have been in progress in this clinic, and the results will be given in another report. Lesses and Myerson⁴ have reported that benzedrine will also diminish the appetite in certain patients. They state that this drug not only relaxes the stomach and intestinal tract, but also alters the mood of the patient and increases his sense of well-being. Atropine may possibly have some slight psychic effect in the doses administered in this study, but its principal effect is upon the gastro-enteric tract. These observations indicate that the action upon the gastro-enteric tract was the major one in decreasing the appetite of our patients with obesity.

SUMMARY

The administration of belladonna alone or with a mild sedative decreased the appetite in 40 of 45 patients. The relative number of patients affected undoubtedly would be less in a larger series of cases. The causes for the decrease in appetite are discussed.

TOXIC EFFECTS OF SULFANILAMIDE, SULFAPYRIDINE, AND RODILONE IN ANOXIA*

G. A. EMERSON, PH.D., D. W. NORTHUP, PH.D., AND
E. J. VAN LIERE, PH.D., M.D., MORGANTOWN, W. VA.

EFFECTS of sulfanilamide on airplane pilots have interested Mackie¹ and Rook² in England, and their communications have received recent comment in the *Journal of the American Medical Association*.³ Mackie reported that a pilot taking a full dose of sulfanilamide just prior to flying exhibited symptoms of anoxemia at an altitude of 13,000 feet. Since the partial pressure of oxygen at this altitude is 97 mm., this corresponds to only a moderate degree of anoxia. These authors state that sulfanilamide or its derivatives lowers the aviator's ceiling, or tolerance to anoxia, by about 5,000 feet. Rook² notes that similar observations have been made in America and Germany. Mackie¹ suggests that the cause of such reactions is an idiosyncrasy in which methemoglobin or sulfmethemoglobin is formed in sufficient amount to decrease significantly the oxygen-combining capacity of the blood.

Apart from the practical aspects of this purported effect of sulfanilamide derivatives, the problem deserves further investigation because cyanosis produced by sulfanilamide is not generally considered to be due entirely to inactivation of hemoglobin, and the effects of anoxia on actions and toxicity of sulfanilamide have not been thoroughly studied. Accordingly, the acute and cumulative toxic effects of three sulfanilamide-type drugs were proposed for study in mice exposed to various degrees of anoxia.

ACUTE EXPERIMENTS

From four to five hours after receiving oral doses of one of the three agents, or of the vehicle, 225 adult white mice, weighing from 18 to 22 Gm. each, were exposed to varying degrees of anoxia. All agents were suspended in 10 per cent aqueous solutions of acacia, and the concentrations adjusted so that all mice received 50 ml. per kilogram of solution. Sulfanilamide was given in a single dose of 20 Gm. per kilogram, and both sulfapyridine and rodilone were given in single doses of 10.0 Gm. per kilogram. Control mice were treated with 50 ml. per kilogram of 10 per cent acacia solution. Intragastric administrations were made with a blunted No. 18 needle, as recommended by Molitor and Robinson.⁴ No deaths occurred immediately after treatment, showing that neither too rapid dilation of the stomach nor aspiration of solution into the lungs occurred.

Doses chosen were in the lower portion of the toxic range of the three compounds, for 3 of 64 mice treated with sulfanilamide, 3 of 59 treated with sulfa-

*From the Departments of Pharmacology and Physiology, West Virginia University School of Medicine, Morgantown.
Received for publication, November 18, 1939.

pyridine, and none of 53 treated with rodilone died during the four- to five-hour period prior to exposure to anoxia. None of 60 control mice which received aeacia alone died before exposure to anoxia. Doses having a definite but low toxicity were purposely chosen to magnify any effects which anoxia might have.

Anoxia was produced in a decompression chamber resembling that of Kolls and Loevenhart.⁵ This tank allows adequate ventilation, and even at very low pressures the air is changed rapidly enough to prevent accumulation of carbon dioxide. From ten to fifteen minutes were allowed for slowly decreasing the tank pressure, according to the final pressure attained.

Control mice, treated with aeacia alone, were always exposed to low pressures simultaneously with mice treated with the drugs.

RESULTS

Four groups of 10 mice treated with sulfanilamide were subjected to anoxia for one hour. One group was exposed to a partial pressure of oxygen of 100 mm., the second group to a partial pressure of oxygen of 80 mm., the third group to a partial pressure of oxygen of 64 mm., and the fourth group to a partial pressure of oxygen of 53 mm. No deaths occurred at these levels, which correspond to approximate altitudes of 12,000, 18,000, 24,000, and 28,000 feet, respectively. All of 20 treated mice survived exposure to a partial pressure of oxygen of 48 mm., which is equivalent to an approximate altitude of 30,000 feet.

The same altitude equivalents and length of exposure were used in testing effects of sulfapyridine on susceptibility to anoxia. One of 10 treated mice died when exposed to a pressure corresponding to an approximate altitude of 18,000 feet, but 20 treated mice survived exposure to pressures equivalent to approximate altitudes of 24,000 or 28,000 feet. One of 15 treated mice died during exposure to a partial pressure of oxygen of 48 mm. (30,000 feet).

Parallel experiments were made with rodilone, except that no mice were exposed to a partial pressure of oxygen of 100 mm. Three of 10 mice died during exposure to a pressure corresponding to an approximate altitude of 28,000 feet. During exposure to a pressure equivalent to an approximate altitude of 30,000 feet, however, none of 20 treated mice died.

Groups of 10 mice treated with aeacia alone were exposed to anoxia for one hour. One group was subjected to a partial pressure of oxygen of 100 mm., a second to a partial pressure of oxygen of 80 mm., a third to a partial pressure of oxygen of 64 mm., a fourth to a partial pressure of oxygen of 53 mm., and a fifth to a partial pressure of oxygen of 48 mm. In the last group a single death occurred.

Mice treated orally with 2.0 Gm. per kilogram of sulfanilamide showed marked prostration and slight convulsions. Degrees of anoxia used in this work had little effect on these symptoms. Mice treated with sulfanilamide were generally much quieter during the period of anoxia than were the control mice.

Treatment with 10.0 Gm. per kilogram of rodilone or sulfapyridine did not produce the prostration or convulsions observed in mice treated with sulfanilamide. Mice in these two groups were indistinguishable from the controls. It is notable that in these groups deaths occurred during anoxia, while no deaths occurred during anoxia in mice treated with sulfanilamide.

CUMULATIVE EXPERIMENTS

The three drugs and the vehicle were given orally, four times a day, for five days to four groups of mice before exposure to anoxia. Doses were spaced at approximately four-hour intervals, so that the mice received treatment for twelve hours each day. Since solution of these agents is slow, the actual time during which the mice were absorbing the drugs probably included at least sixteen hours each day. This procedure was adopted in order to follow as closely as possible the clinical use of these agents when intensive treatment is applied.

Also, single doses were low, although they were greater than the equivalent clinical doses on a weight basis. Doses used were below those which might be expected to produce any marked toxic symptoms. Sulfapyridine and rodilone were administered in single doses of 250 mg. per kilogram, corresponding to a daily dose of 1.0 Gm. per kilogram or a total dose of 5.0 Gm. per kilogram for the five days. Sulfanilamide was administered in single doses of 100 mg. per kilogram, corresponding to a daily dose of 400 mg. per kilogram or a total dose of 2.0 Gm. per kilogram for the five days.

All mice received these doses in single administrations of 0.1 ml. per 20 Gm. of solution, or a total of 100 ml. per kilogram of fluid in the five-day treatment period. The vehicle was 10 per cent acacia solution, and control mice received equivalent amounts of this. Since the mice voluntarily drank large amounts of water in addition to this, probably no disturbance in fluid balance occurred, although the daily amount of administered solution, 20 ml. per kilogram, is equivalent to the average daily urinary output in man. If hydration did occur, however, its possible effects on tolerance to anoxia are controlled, since the control mice received the same amounts of fluid.

Mice were weighed before the first treatment, on the third day of treatment, and on the sixth day, immediately before exposure to anoxia. The mean body weights of each group for these days were, respectively: for the controls, 21, 23, and 20 Gm.; for the group treated with sulfapyridine, 21, 23, and 20 Gm.; for the group treated with rodilone, 22, 22, and 20 Gm.; and for the group treated with sulfanilamide, 21, 20, and 19 Gm. Statistical examination of the standard errors of differences between these means revealed no significant changes. The slightly lower values on the sixth day were the result of a twelve-hour fast before exposure to anoxia.

RESULTS

On the sixth day, ten hours after the last treatment, the mice were exposed to anoxia for one hour. Twenty mice of each group were subjected to a pressure corresponding to an approximate altitude of 30,000 feet. One of the control mice which had been treated with acacia alone and 2 of the mice which had received rodilone died during anoxia. No deaths occurred during anoxia among mice which had been treated with sulfanilamide or sulfapyridine. At no time did any of the mice show the prostration or convulsions characteristic of acute sulfanilamide toxicity.

DISCUSSION

The results show that large oral doses of neither sulfanilamide nor sulfapyridine increase susceptibility to anoxia, nor do these agents exert a cumulative

effect which is detrimental to anoxic animals. This evidence might be expected from the success of the clinical use of these agents in pneumonia.

Results with rodilone are not sufficiently significant, when examined by the criteria of Loewenthal and Wilson,⁶ to permit the conclusion that rodilone has any effect on tolerance to anoxia. Molitor and Robinson⁴ comment on the marked cyanosis developed during repeated administration of rodilone. Although the careful studies of Harris and Michel,⁷ and Long, Bliss, and Feinstone,⁸ show the presence of methemoglobin or sulfmethemoglobin, or a fall in oxyhemoglobin content, in the blood of patients treated with sulfanilamide or sulfapyridine, it must be concluded from the present results that neither of these processes is important in mice treated intensively with any of the three compounds studied. Hematuria, if it occurred, was not sufficiently grave to produce an anemia severe enough to lower tolerance to anoxia.

The results may be considered confirmatory of Brun's⁹ finding that these drugs do not increase the metabolic rate. Certainly there is no evidence of increased need of oxygen in the treated mice.

Of more practical importance than the present toxicity studies is the possible effect of sulfanilamide-type compounds on functions involved in precise orientation of persons. Rook² and Robertson¹⁰ have indicated the possible dangers of allowing patients treated with sulfanilamide to engage in activities requiring precise judgment of orientation and speed. Experimental studies on man should be made to evaluate this point properly. In addition, the effect of the disease, for which sulfanilamide is being given, on judgment and coordination, must also be considered.

SUMMARY

Mice treated with single large oral doses of sulfanilamide, sulfapyridine, or rodilone showed no increased susceptibility to anoxia. Repeated treatment with smaller doses of these three agents given orally, four times a day, for 5 days also did not increase susceptibility to anoxia.

We are grateful to Dr. Hans Molitor, of the Merck Institute for Therapeutic Research, for generously supplying sulfapyridine (Dagenan) and rodilone (di-p-acetylamino-phenyl-sulfone). All rodilone used was of the same preparation, designated as lot 144.

INFLUENCE OF SODIUM CHLORIDE CRYSTALLIZATION BY CEREBROSPINAL FLUID*

SAMUEL BURACK, M.D., AND PAUL B. SZANTO, M.D.
KANKAKEE, ILL.

FOLLOWING the evaporation of a salt solution there results crystal formation which is specific for each salt and is the so-called crystal habit of the salt. Various workers have shown that the crystal formation of a salt may be easily affected by many factors. The minutest impurity in the salt solution will influence the crystal habit. Semenenko and Shikhobalava¹ showed that the surface tension of the salt solution was the most important factor influencing the crystallization. Changes in the surface tension are reflected by changes in the crystal habit. These workers showed that the crystallization of sodium nitrate by evaporation is hardly influenced by substances which cannot change the surface tension of this salt. By the addition of surface-active substances a typical change of the crystal configuration is possible. Among the most important surface-active substances are albumin and globulin. These physicochemical facts were first used by Pfeiffer,² who noted that the addition of minute quantities of blood influenced the crystallization of a copper chloride solution. He further observed that blood from a tuberculous or cancerous patient gave a different type of crystal formation than did normal blood. He felt that by this method a serologic diagnosis of certain diseases was possible.

Tomeseo and his co-workers³ used the same principle for the study of the cerebrospinal fluid. They added minute quantities of cerebrospinal fluid to physiologic saline solution. They then studied the results of the crystallization by evaporation of this mixture at a temperature of 75° C.

The evaporation of 3 drops of physiologic saline solution results macroscopically in the formation of an outer ring surrounding an empty space. Microscopically, the sodium chloride crystals have a cubical shape. The addition of normal cerebrospinal fluid changes this picture. Tomeseo and his associates found that the normal cerebrospinal fluid is able to change the crystallization in a dilution of 1:20 up to 1:60 or 1:80. Macroscopically, the evaporation of 3 drops on a slide shows a crystalline circumference enclosing a translucent layer. With higher dilutions this translucent layer disappears, and one sees only empty spaces, i.e., the same picture as seen without the addition of cerebrospinal fluid. Microscopically, the translucent area consists of rosettes, concentric circles, parallel lines, and needles.

*From the Kankakee State Hospital, Kankakee, Dr. G. W. Morrow, managing officer.
Received for publication, November 27, 1933.

In cases of general paresis Tomesco and his co-workers found typical changes in the crystal habit. Macroscopically, the central translucent layer was found to be present in dilutions up to 1:120. Microscopically, they found concentric circles, parallel lines, and fine needles, but the organization of the pattern was much finer than that of normal cerebrospinal fluid. The concentric circles around one or two cuboid sodium chloride crystals were especially finely organized. In all cases the cerebrospinal fluid showed positive Pandy and Nonne-Apelt tests, i.e., signs of increased protein content. In a later publication Tomesco and his collaborators stressed the fact that they found the so-called mixed form of crystallization in such mental diseases as schizophrenia and melancholia. This consisted of pictures which were between the normal and pathologic types. They felt that the increased protein is a very important factor but not the only one which can explain the reactions.

Finkelman⁴ used the technique of Tomesco in a large series of cases. He examined 35 specimens of cerebrospinal fluid of patients with general paresis and found typical pathologic crystal patterns in 33 specimens. Of 17 persons with functional epilepsy, 11 showed normal pattern and 6 were of the mixed type. Of 16 persons with dementia praecox, 10 were normal and 6 were of the mixed type; in all these patients the Ross-Jones test was negative. Seventy-one specimens of spinal fluid from persons with nonneurologic disorders were all negative.

Recently Selzer⁵ used Tomesco's technique but obtained different results. Although he found in the main in normal persons and in persons with pathologic disorders the same results as Tomesco, he is of the opinion that this method is without practical value because the formation of the pattern depends so much upon minute changes of the surface tension that sometimes drops from the same dilution evaporated on different slides, but at the same temperature, may show a different pattern formation. Selzer showed that there is an exact mathematical parallelism between the degree of the albumin content and the pattern formation.

The results obtained by these previous workers seemed of sufficient importance to us to prove the diagnostic value of this new reaction. In order to exclude any subjective factor the clinical diagnosis of the fluids examined was not disclosed to the examiner.

TECHNIQUE

We followed the method used by Tomesco and his co-workers and Finkelman. Briefly, this consisted of setting up ten test tubes of 0.8 per cent sodium chloride solution. The first tube contained 1 c.e., the second, 2 c.e., with increasing amounts up to 10 c.e. in the tenth tube. To each tube was added 1 drop of cerebrospinal fluid, and the tube was well agitated. Three drops of the contents of each tube were placed on separate slides, and the slides in turn were placed in an oven at 75° C., until the fluid was entirely evaporated. The slides, tubes, and pipettes used must be very clean and contain no impurities. The temperature is very important. We found that if the slides were kept at room temperature, or even up to 50° C., the crystallization shows a different picture.

The effect of other substances in influencing the crystal habit was shown by the following experiment: Using cerebrospinal fluid from a patient with general paresis, a typical organization pattern was obtained. To the same fluid in the test tube we now added 1 drop of an insulin solution; this led to the disappearance of the previous characteristic crystallization. The interpretation of the results is important. It seemed to us that the previous readings as positive, negative, or mixed type were not sufficiently exact. We also felt that the macroscopic picture had no diagnostic value in comparison to the microscopic picture. Normal or negative fluids show the following picture: Macroscopically, in a dilution of from 1:20 to 1:80 there is a translucent layer surrounded by a crystalline ring. This layer gradually disappears with higher dilutions. Microscopically, the translucent area consists of rosettes, concentric circles, parallel lines and needles (Fig. 1). In higher dilutions the pattern gradually disappears.

Fig. 1.—Crystallization of sodium chloride influenced by normal cerebrospinal fluid, dilution 1:80 (photomicrograph 1:80).

We divided the positive cases into three-, two-, and one-plus reactions. A three-plus fluid was characterized as follows: Macroscopically, there were no empty spaces in the translucent layer, even in a dilution of 1:200, i.e., 1 drop of spinal fluid plus 10 c.c. of saline solution. Microscopically, there were concentric circles, parallel lines, and fine needles, but the organization of the pattern was much finer and of a different nature (Fig. 2). The characteristic sign of a strongly positive pathologic fluid was the presence of a central cuboid crystal surrounded by many fine concentric rings. This is called good organization of the pattern and may be found in dilutions of 1:200 or even higher.

In a two-plus fluid the microscopic picture was the same qualitatively, but quantitatively there was a difference because the good organization was found up to only 1:140 or 1:160 dilution. The one-plus fluid shows a good organiza-

tion only in dilutions up to 1:100 or 1:120. As doubtful fluids we considered those cases where there was a more or less good organization up to 1:80. Sometimes one can find, even in normal spinal fluids in low dilution, a good organization pattern in the region just inside the peripheral crystalline ring. We do not consider this a pathologic finding.

Fig. 2.—Crystallization of sodium chloride influenced by cerebrospinal fluid from a case of general paresis, dilution 1:200 (photomicrograph 1:80).

MATERIAL

We examined 263 persons. This consisted of 151 persons with general paresis, 46 with dementia praecox, 26 with chronic alcoholism, 8 with idiopathic epilepsy, 8 with mental deficiency, 4 with psychoneuroses, one with multiple sclerosis, one with pachymeningitis hemorrhagica interna, one with manic-depressive insanity, 8 with cerebral arteriosclerosis, and 9 without psychosis.

General Paresis.—Many of the 151 patients had been treated for varying periods of time, and some had completely negative serologic and spinal fluid findings. Of these, 31 gave a three-plus crystallization; 38, a two-plus; 46, a one-plus; 2 gave a doubtful and 34 a negative crystallization. In other words, the crystallization was positive in 115, or 76 per cent, of the cases.

Of more importance is a comparison between the crystallization finding and the other laboratory findings.

1. Of the 31 persons with a three-plus crystallization the blood Kahn test was positive in 27, and the spinal fluid Wassermann test was positive in all. The Lange colloidal test gave a typical paretic curve in 22 persons, a middle zone curve in 8, and a negative result in 1. The Ross-Jones test was positive in 12 persons, gave a trace of globulin in 12, and was negative in 7; i.e., this test was negative in 22 per cent of strongly positive crystallizations. The cell count was above 10 in 15 cases.

2. Of the 38 persons with a two-plus crystallization the blood Kahn test was positive in 27, and the spinal fluid Wassermann test was positive in 36. The Lange colloidal test gave a typical parietic curve in 4 persons, a middle zone curve in 30, and a negative result in 4. The Ross-Jones test was positive in 2 persons, gave a trace of globulin in 16, and was negative in 20; i.e., this test was negative in 52 per cent of the cases. The cell count was above 10 in 14 cases.

3. Of the 46 persons with a one-plus crystallization the blood Kahn test was positive in 30, and the spinal fluid Wassermann test was positive in 42. The Lange colloidal test was typical in one person, gave a middle zone in 33, and was negative in 12. The Ross-Jones test was positive in 2 persons, gave a trace of globulin in 10, and was negative in 34; i.e., this test was negative in 73 per cent of the cases. The cell count was above 10 in only 7 cases.

4. One of the two persons with doubtful crystallization showed a positive blood Kahn test; both showed negative spinal fluid Wassermann tests and negative Lange and Ross-Jones tests. The cell count was not increased.

5. Of the 34 persons with negative crystallization the blood Kahn test was positive in 7. Both the spinal fluid Wassermann and the Lange tests were negative in every case; in only one case did the Ross-Jones test show a trace of globulin and only in this case was the cell count above 10.

6. Of the 115 persons with positive crystallization the Ross-Jones test was positive in only 54, or 46 per cent of the cases. The Lange test was positive in 98, or 85 per cent of the cases. The spinal fluid Wassermann test was positive in 108, or 93 per cent of the cases. The cell count was above 10 in only 36, or 31 per cent of the cases. These results seem to indicate that the results of the crystallization show a parallelism first to the spinal fluid Wassermann test, and second, to the Lange test.

7. The crystallization was positive in every case in which the spinal fluid Wassermann test was positive, and in every case in which the Lange test gave a typical or middle zone curve. On the other hand, there were other cases in which the crystallization was positive, but the Lange, Ross-Jones, and spinal fluid Wassermann tests were negative.

Dementia Praecox.—We examined 46 persons with various types of dementia praecox. The crystallization was positive in 7 persons, doubtful in 4 and negative in 35. In the 7 persons with positive crystallization the blood Kahn test was positive in every case, the spinal fluid Wassermann test was positive in 4, the Lange test was of the middle zone type in 2, and the Ross-Jones test showed a trace of globulin in one case. In the doubtful cases the blood Kahn was positive in one case. In each one of the 7 positive cases syphilis was associated with the dementia praecox.

Chronic Alcoholism.—Of the 26 persons with chronic alcoholism one gave a positive and one gave a doubtful crystallization. No sign of syphilis was noted in either person.

Epilepsy.—Of the 8 persons with epilepsy one showed a two-plus crystallization. In this person the blood Kahn and the spinal fluid Wassermann tests were positive, and the Lange test was typical.

Mental Deficiency.—Of the 8 persons with mental deficiency 2 gave a doubtful crystallization, both of whom had positive blood Kahn tests but negative spinal fluid tests.

Psychoneuroses.—Of the 4 persons with psychoneuroses one gave a positive and one a doubtful crystallization. The person with the positive crystallization showed negative blood and negative spinal fluid tests, but his history stated that he had been treated for syphilis. The patient with the doubtful reaction had a positive blood test.

Cerebral Arteriosclerosis.—Of the 8 persons with cerebral arteriosclerosis two had positive crystallizations and positive blood Kahn tests but negative spinal fluid tests.

Without Psychosis.—All the remaining patients gave negative results.

COMMENT

A review of the preceding problem brought up the question of the factor or factors involved in the crystallization. Tomesco and his co-workers at first felt that the albumin-globulin content of the spinal fluid was the important factor because they noted that these substances are able to change the surface tension of the solution. In a later publication they stated that this cannot be the only factor, since they found strong pathologic or mixed type crystallization in persons with normal cerebrospinal fluid. Selzer stressed the increased albumin content as the only responsible factor. To prove this he showed that by removing the albumin of the spinal fluid the remaining fluid had no influence on the crystallization. By removing the albumin from normal and pathologic spinal fluids, as in general paresis, we got the same results as Selzer. However, we do not feel that we should draw the same conclusion as he did, i.e., that the only factor involved is the increased albumin, for it is possible to eliminate other unknown factors by removing the albumin. Perhaps besides the quantitative increase of protein in the spinal fluid, certain qualitative changes of the proteins are important, or a change in the albumin-globulin ratio may be responsible. From a practical point of view our results differed somewhat from those of previous workers. In case of general paresis our results were similar. However, in those cases of dementia praecox where we obtained a positive crystallization, syphilis was present in almost every case. In an occasional instance, alcohol seemed to be the only predisposing factor. It was also interesting to note in cases of general paresis that the crystallization phenomena seemed to be more sensitive than the colloidal gold curve.

We feel that further studies are indicated to discover the factors responsible for the crystallization phenomena.

SUMMARY

We examined the effect of normal and pathologic cerebrospinal fluid on the crystallization of sodium chloride. Spinal fluid of general paresis influences the crystal habit of sodium chloride in a typical manner.

OBSERVATIONS ON THE INTERRELATIONSHIP OF CAPILLARY, PLATELET, AND SPLENIC FACTORS IN THROMBOCYTOPENIC PURPURA*

R. H. EGERTON ELLIOTT, JR., M.D., AND MARY A. WHIPPLE
NEW YORK, N. Y.

IN CASES of thrombocytopenic purpura a discrepancy between the degree of clinical bleeding and the level of the platelet count is not infrequently observed. One of us in a recent publication¹ was able to show that when this occurs the resistance of the capillaries, as measured by Dalldorf apparatus, tends to parallel the degree of clinical bleeding rather than the platelet level. In the same article attention was also called to the facts that following the performance of splenectomy for the relief of purpura, the capillary resistance rises with abrupt rapidity, that it often precedes in this respect the elevation of the platelet count, and that it may, therefore, be the first measurable sign of clinical improvement. In addition, it was concluded as a corollary that the suction test for capillary resistance was a useful method of measuring the activity of this disease and that in certain instances it was of more value in this connection than the enumeration of the blood platelets.

Since the publication of these investigations, we have been able to confirm the foregoing observations on numerous occasions. The number of consecutive cases of purpura which have been subjected to splenectomy and so studied in this clinic now totals 12. In every instance the results of our observations on capillary resistance have been essentially the same.

As a control to the latter observations, resistance determinations have been performed upon five individuals undergoing splenectomy for conditions

*From the Spleen Clinic of the Presbyterian Hospital and the Department of Surgery of the College of Physicians and Surgeons, Columbia University, New York.
Received for publication, November 27, 1939.

other than purpura. In only one instance was any alteration in resistance noted, and this proved to be a slow rise, quite unlike those observed in the purpura cases, in a patient whose spleen was removed to facilitate the excision of a pancreatic adenoma. In this instance, the change may well have been due to the general improvement of the patient following the removal of the tumor.

As additional controls the capillary resistance was followed in five individuals undergoing relatively simple abdominal operations in which the spleen was not removed. In none of these patients were the resistance values altered significantly.

To explain the relatively common phenomenon of the discrepancy between the platelet level and the intensity of the hemorrhagic manifestations in purpura, it becomes necessary to assume the presence of both a capillary and platelet factor in the mechanism of the disease. Bedson² gives the credit for advancing this hypothesis to Pierre Nolf, who offered the following ingenious experimental evidence in its support:

Using rabbits as subjects, he produced a marked, but transitory, thrombocytopenia by the intravenous injection of agar, and found that no purpura resulted. He then damaged the capillary endothelium of other rabbits by the intravenous administration of an anti-rabbit red blood cell serum. Again no purpura resulted, despite the fact that actual injury to the capillary endothelium could be demonstrated microscopically. When, however, he combined the two procedures, administering to the same animal first the anti-red blood cell serum and then the agar, i.e., when he added a thrombocytopenia to capillary damage, a marked degree of purpura resulted.

Inasmuch as our clinical investigations seemed not only to support Nolf's theory but also to establish the suction test as a relatively accurate method of measuring the severity of the disease process in purpura, we decided to repeat Bedson's experiments, hoping that by following the resistance of the capillaries we could better evaluate the individual importance of the capillary and platelet elements in the mechanism of this disease. In addition, it also seemed desirable to investigate the relationship of the spleen to these two factors. Therefore, for the sake of completeness and because of certain advantages which will be apparent later, we adopted the antiplatelet serum method of producing purpura as an alternative to the technique of Bedson described in the preceding paragraph.

TECHNIQUE

We employed then two separate and distinct techniques in the production of experimental purpura. They were (1) the antiplatelet serum method and (2) the method of Bedson. A brief description of each method is presented. If more detailed information is desired, the papers of some of the many investigators who have used essentially similar techniques may be consulted.^{2,3} Light-skinned, male chinchilla rabbits, weighing between 2 and 3 kg., were used as the experimental animals throughout.

The Antiplatelet Serum Method.—In preparing the platelet antigen for the production of purpura by means of antiplatelet serum, the blood of two rabbits was drawn from the heart under nembutal anesthesia into an equal quantity of oxalated saline (sodium chloride 0.9 per cent and potassium oxalate 0.2 per cent). After centrifuging rapidly for one-half hour, the buffy coat was pipetted off and washed three or four times in normal salt solution to remove the remaining red blood cells as completely as possible. The yield, generally averaging between 1.5 and 2.5 c.c., was suspended in saline and injected intravenously into dogs. Four such injections were given at weekly intervals. A week after the last injection the dogs were bled and the desired quantity of antiplatelet serum was obtained. The serum so prepared was then injected intraperitoneally into rabbits, a dosage of 1.5 c.c. per kilogram of body weight being generally sufficient to produce a moderately severe thrombocytopenic purpura of from three to five days' duration (see Chart 1).

Chart 1.—Experimental thrombocytopenic purpura by means of antiplatelet serum showing the lag of the capillary resistance behind the platelets in returning to normal. Note also the relatively short duration of the purpura.

Bedson's Method.—The technique used in the preparation of an anti-red blood cell serum for the production of purpura by the previously outlined method of Bedson was essentially similar to that employed in the preparation of antiplatelet serum. At weekly intervals dogs were injected intravenously with a saline suspension of 2 c.c. of washed rabbit red blood cells, and a week after the fourth injection the desired amount of anti-red blood cell serum was obtained.

The agar-treated serum to be used in conjunction with the anti-red blood cell serum was made up as follows: One part of a suspension of 0.5 per cent agar in saline was mixed with four parts of fresh normal rabbit serum. The mixture was then incubated at 37.5° C. for two hours and allowed to stand at room temperature overnight. The following day it was centrifuged to remove any macroscopic agar and the clear supernatant serum was pipetted off. To produce purpura the anti-red blood cell serum was first injected intravenously into a rabbit, the dosage being 0.85 c.c. per kg. Three or four hours later the agar serum was administered to the same animal in similar fashion, the dosage in this instance being 5 c.c. per kilogram of body weight. The resulting purpura was to all appearances similar to that produced by antiplatelet serum, but more severe (Chart 2a).

OBSERVATIONS UPON NORMAL RABBITS

Fifty-six rabbits were used in the course of our investigative work. Upon 54 of these at least one or more control determinations were made. The determinations were carried out before subjecting the animals to experimental

procedures which would in any way affect their apparent good health. These determinations included hemoglobin values, red and white corpuscles, differential blood counts, bleeding and clotting times, clot retractility estimations, platelet counts, and capillary resistance determinations. This information is summarized in Table I, which includes the maximum, minimum, and mean values, together with the number of initial observations for each determination.

TABLE I
CONTROL VALUES

	NO. OF INITIAL OBSERVATIONS	MAXIMUM	MINIMUM	MEAN
Hemoglobin*	43	90	71	79
Red blood cell count	44	6,900,000	5,000,000	6,000,000
White blood cell count	42	12,100	5,600	9,100
Differential count†				
Polymorphonuclears	40	71	26	49
Lymphocytes	40	66	18	42
Monocytes	40	8	0	4
Basophiles	40	10	0	2
Eosinophiles	40	6	0	3
Bleeding time‡	41	4'00"	1'10"	2'14"
Clotting time	40	3'00"	0'45"	1'41"
Clot retractility§	22	24+ hr.	1½ hr.	
Platelets¶	54	438,000	178,000	298,000
Capillary resistance	33	50 plus	15	

*Sahl.

†Figures given in per cent.

‡Duke's method.

§In 7 cases there was no retraction after twenty-four hours.

¶Direct method.

||Figures given are in centimeters of mercury negative pressure.

The figures in Table I for the hemoglobin content and cellular elements of the blood agree closely with those of the majority of other observers who have employed the same technical methods as were used here. Determinations of the bleeding time were not always satisfactory, as the test was done by pricking the marginal ear vein, the state of contractility of which was found to influence markedly the results in several instances. It was likewise found that estimations of clot retractility on the normal animal were of little use as control observations, for in a third of the animals upon which the test was performed, retraction of the clot was either delayed or failed to take place at all.

As in our clinical work, all capillary resistance determinations were done with the Dalldorf apparatus. The animals were shaved prior to testing, and the tests were carried out on the skin of the abdominal wall, the technique used being identical in every respect with that employed clinically.

The normal figures for capillary resistance in the rabbit were slightly higher than those we observed in human beings. In man we have found it ranged between 20 and 35 cm. of mercury negative pressure when taken on the forearm just below the antecubital fossa;¹ in the rabbit it ranged between 30 and 40 cm. of mercury negative pressure, with a mean value of approximately 35. The variation observed between rabbits tended to be greater than the variation between human beings, though an effort was made to minimize this discrepancy as far as possible by selecting light-skinned animals of the same

breed. The reason for this greater variation is due to the fact that greater individual differences exist in the texture, color, and thickness of the skin among rabbits than among human beings.

Two other factors that tended to influence the results of resistance determinations were shaving and the application of antiseptic solutions to the skin of the abdominal wall immediately prior to operative procedures. For this reason, when shaving was indicated, it was carried out twenty-four hours in advance of the performance of any determinations and iodine was generally omitted from the preoperative preparation of the skin, or if it was used, it was applied in weak dilutions, care being taken subsequently to remove it completely.

Despite the number of factors capable of influencing the results of this test, there was little variation between readings taken on different areas of the abdominal wall in the same animal, provided that the test was not performed on the flanks or in the groin.

Undoubtedly the suction test for capillary resistance is not as accurate in rabbits as it is in human beings. For this reason, we do not regard a change of resistance in rabbits as being of much significance unless it is greater than five points. Notwithstanding this, we feel that within broad general limits the test does give a reasonably accurate estimation of the state and change of resistance in the capillaries of the animals under discussion.

PROCEDURES

In our attempt to study experimentally the mechanism of the disease process in purpura, we pursued our investigations along lines as nearly parallel with our clinical studies as possible. With this in mind, the thrombocytopenic purpura produced by antiplatelet serum and Bedson's anti-red blood cell serum-agar serum methods was studied first. Subsequently, the effect of splenectomy both before and after the production of purpura by these methods was investigated.

PRODUCTION OF PURPURA

No difficulty was experienced in the production of purpura by means of either technique used. It was found that following the employment of these methods a thrombocytopenic purpura was produced which resembled the clinical form in every respect save that of duration, the experimental syndrome lasting usually no longer than five days. Of considerable interest was the fact that the capillary resistance which dropped along with the platelets generally required a much longer time to return to normal levels than did the latter (Chart 1).

Like Bedson, we found that the injection of anti-red blood cell serum alone, or of agar serum alone, did not produce purpura. In addition, these procedures had no appreciable effect upon the capillary resistance. We found, furthermore, that as a whole the animals subjected to Bedson's method developed a more severe grade of purpura than did those injected with anti-platelet serum. Charts 1 and 2a depict graphically the typical course of events in animals subjected to both of the afore-mentioned techniques.

SPLENECTOMY AND EXPERIMENTAL PURPURA

A. Operative Controls.—In order to parallel our clinical studies on splenectomy and to establish control groups for similar experimental investigations, the effect both of simple laparotomy and of splenectomy upon the blood values and the capillary resistance of normal animals was investigated. Ether anesthesia was employed in both procedures and the operative technique in each was identical, the only difference between the two operations being that in one the spleen was removed, and in the other it was exposed but not disturbed.

Chart 2a.—Experimental thrombocytopenic purpura by means of the combined administration of antiserum and agar serum. At autopsy this animal showed a very severe purpura with abundant hemorrhages into the mesenteries, the pancreas, and the subserosal tissues of the intestines. *b*, Experimental thrombocytopenic purpura following splenectomy performed during the combined administration of agar serum and antiserum. Autopsy showed severe purpura.

Following the performance of simple laparotomy, a slight rise in platelets was observed in each animal, the maximum and minimum increments for three animals thus followed being 96,000 and 19,000, respectively. The increments in the latter values following removal of the spleen, however, were considerably greater and averaged between 100,000 and 200,000 (see Chart 3b). In neither of these control procedures was the capillary resistance altered significantly.

B. Protective Effect of Splenectomy.—Bedson⁷ has found that in guinea pigs splenectomy affords a varying degree of protection against the purpura produced by antiplatelet serum when this operation is performed prior to the administration of the serum. Because we wished to determine whether the same results obtained in rabbits and whether the performance of splenectomy before the injection of antiplatelet serum had any effect upon the capillary resistance, we repeated Bedson's experiment upon three animals.

Accordingly, the animals' spleens were removed, and six or seven days later, during the course of the ensuing platelet rise, antiplatelet serum was administered intraperitoneally. Despite the fact that the dose of the latter

was increased over the usual amount in all the animals and even administered in double the customary quantity in one, none of the rabbits developed purpura and none showed any change in capillary resistance (Chart 3b).

C. Splenectomy Following the Injection of Antiplatelet Serum.—The object of this group of experiments was to determine whether the removal of the spleen was as beneficial in experimental purpura as in the clinical form of the disease. Because of the relatively short duration of the purpura produced by the injection of antiplatelet serum, it was decided that it would be necessary to perform splenectomy early in the course of the disease. Therefore, as soon as a material drop in the platelet level and capillary resistance had occurred following the injection of the serum, the spleen of the animals was removed. It was realized that this was hardly a fair parallel to the circumstances obtaining when this operation is performed for the relief of purpura in man, and yet, for the reasons mentioned above, we could hardly do otherwise.

Chart 3a.—Experimental effect of splenectomy performed after injection of antiplatelet serum.

Chart 3b.—Protective effect of antiplatelet serum following splenectomy performed after moderate purpura.

Four animals, then, were injected intraperitoneally with antiplatelet serum. Between two and three hours later splenectomy was performed, for it was generally found that material depressions in both capillary resistance and platelet values had occurred within this space of time.

In each of the 4 animals so treated, a purpura of varying intensity developed, despite the fact that in none did the platelet level drop below 170,000. The findings were corroborated at autopsy on each of the animals. As will be seen in Chart 3a, a fall in capillary resistance was produced which lagged well behind the platelets in returning to normal.

D. Splenectomy and Experimental Purpura Produced by Bedson's Method.—In these experiments the decision as to where in the course of the procedure to intercalate splenectomy was particularly difficult. In the first place, the

same handicap existed here as was met with in the preceding experiment with regard to the brevity of the purpura. In the second place, it was obvious from earlier experiments that if the operation was performed immediately following the administration of agar serum, the animals would in all probability not survive the trauma incident to operation, together with the rapid development of a severe purpura, if such should occur. Therefore, it was felt that if the operation were performed shortly *before* the injection of the agar serum, but sufficiently long *after* the administration of the anti-red blood cell serum to allow the latter to affect the capillaries, the animals would have a better chance of survival. In addition, by this procedure we would be able to determine whether splenectomy negated to any extent the capillary-damaging effect of the anti-red blood cell serum.

Accordingly, splenectomy was performed on three rabbits between two and three hours after the administration of the anti-red blood cell serum. As soon as the animals had recovered from the effects of the anesthesia, agar serum was injected.

Severe purpura developed in all the animals (see Chart 2b). Not only did splenectomy fail to alter the effectiveness of the anti-red blood cell serum, but as nearly as could be determined it in no way lessened the severity of the resulting thrombocytopenic purpura, the presence of which was confirmed at post mortem on each of the animals.

COMMENT

From the foregoing investigations it seems apparent that the administration to rabbits of either antiplatelet serum, or of agar serum in combination with anti-red blood cell serum, is an eminently satisfactory method of producing in these animals a thrombocytopenic purpura which closely resembles the disease as seen clinically. It is worth emphasizing, however, that the experimental purpura so produced is of short duration and, to all appearances, only in this respect does it differ from the clinical syndrome. In producing purpura by the combined administration of anti-red blood cell serum and agar serum, we were able to confirm Bedson's results with this method, which, it will be remembered, were offered as evidence in support of Nolf's theory that both a capillary and a platelet factor are present in the mechanism of this disease and are necessary to its production.

From the results of Bedson's work and our own, it seems apparent that when either a capillary-damaging factor in the form of an anti-red blood cell serum, or a platelet-reducing factor in the form of an agar serum acts alone, it is incapable of producing purpura. It is equally evident, however, that when these two factors act together in the same animal, purpura results. Furthermore, from our investigations we have been able to show that, acting alone, neither one of these two factors materially alters the resistance of the capillaries, but that acting collectively, they do.

We have shown that splenectomy in rabbits neither affects the individual potency of the afore-mentioned capillary-damaging and platelet-reducing agents.

nor alters their combined efficacy in the production of purpura. Furthermore, while we have confirmed and extended to rabbits Bedson's results on the protective effect of splenectomy performed prior to the administration of antiplatelet serum, we have, on the other hand, also been able to show that the performance of this operation following the administration of this serum affords little or no protection against the subsequent development of purpura.

In addition, our experiments have demonstrated that simple laparotomy and splenectomy in the normal rabbit do not affect the resistance of the capillaries, but do cause an increase in the number of platelets, which is of considerably greater extent in the latter operation than in the former. These observations lead us to feel that, as intimated by Bedson, the protective effect of splenectomy performed prior to the injection of antiplatelet serum is purely an indirect one and is due solely to the physiologic increase in the number of platelets which follows this operation. Additional confirmation of this would seem to lie in the fact that following the production of thrombocytopenic purpura by either the antiplatelet serum method or the agar serum method, and irrespective of whether the spleen was removed or not, the resistance of the capillaries undergoes a marked drop and in most instances does not return to its original value until well after the platelet count has resumed its normal level.

DISCUSSION

Though the thrombocytopenic purpura produced by the serologic methods herein described closely resembles in its manifestations the clinical form of this disease, there is no justification for assuming that the role of the spleen in the experimental syndrome is anything other than a minor one and of secondary importance. Certainly our experimental work, as well as that of Bedson, would seem to argue against such an assumption. On the other hand, the almost instantaneous rise in capillary resistance and the cessation of bleeding which follows removal of the spleen in idiopathic thrombocytopenic purpura is evidence that in the clinical form of the disease the role of the spleen is primarily an active one and of major importance. Further evidence for this contention is to be found in the fact that the afore-mentioned increase in the resistance of the capillaries and the alleviation of the hemorrhagic symptoms takes place too soon after operation to be accounted for by the subsequent increase in the number of platelets.

From our clinical as well as from our experimental work, we feel that we have definite evidence of the existence of both capillary and platelet factors in the mechanism of the disease process in thrombocytopenic purpura. In addition, we believe from our observations that the decrease in the resistance of the capillaries seen in this disease is probably the result of the combined action of these two factors. The fact that the capillary resistance tends at times to be dissociated from the platelet level makes us feel that the capillary factor is probably the more important of these two elements, if not in the initiation of the manifestations of the disease, at least in their maintenance.

SUMMARY AND CONCLUSIONS

1. A study of experimental thrombocytopenic purpura produced in rabbits by serologic methods has been made.
2. The relationship of splenectomy to the bleeding tendency, capillary resistance, and platelet count in thrombocytopenic purpura has been discussed.
3. In the absence of purpura, removal of the spleen in man and in rabbits does not affect the capillary resistance.
4. The suction method of measuring capillary resistance is a useful means of estimating the activity of the disease process in experimental as well as in clinical thrombocytopenic purpura.
5. It seems likely that both a platelet-reducing and a capillary-damaging element are present in the mechanism of the disease process in thrombocytopenic purpura and that both are necessary to the production of the disease.
6. The decrease in the resistance of the capillaries, which is seen in thrombocytopenic purpura, is probably the result of the combined action of the platelet and capillary factors.
7. Particular attention is directed to the importance of the capillary factor in thrombocytopenic purpura.
8. In experimental thrombocytopenic purpura produced by serologic methods, the role of the spleen is probably of secondary importance.
9. Evidence is advanced to support the contention that in idiopathic thrombocytopenic purpura the role played by the spleen is an active one and of major importance.

HISTAMINE THERAPY IN ALLERGY

LEON D. PORCH, M.D., MACON, GA.

A REVIEW of the literature relative to the use of histamine in the treatment of allergic disturbances indicates that this substance is perhaps one of the best available agents for alleviating the discomfort caused by these disorders, particularly skin conditions characterized by wheal and edema formation, erythema, pruritus, and the exudative diathesis. Recently, the role of allergy in peptic ulcer has been considered, and certain cases have been found to be associated with allergic manifestations. In this paper the therapeutic effect of histamine in urticaria and other skin lesions and in gastrointestinal ulceration will be evaluated.

Histamine was found in putrid soybeans by Yoshimura³ in 1909, and was isolated from ergot in 1910 by Dale and Barger,³ who also found it to be present in the intestinal mucosa. Chemically, histamine results from the decarboxylation of histidine, and it may be formed by (1) chemical decarboxylation, (2) bacterial decomposition, (3) ultraviolet radiation, and from (4) di-amino-acetone by chemical synthesis. Histidine is widely distributed in the body, being most abundant in such tissues as the intestines, liver, and lungs.³

In 1911 Dale and Laidlow observed that histamine may cause the typical symptoms and pathology of anaphylaxis when injected into normal animals. It caused a drop in blood pressure when injected intravenously into dogs, and it produced an increased capillary permeability or an edema. They showed, however, that the reaction of histamine differs from true anaphylaxis, in that histamine is still capable of producing strong reactions in the uterine strip even though the latter has been desensitized by treatment with specific serum. Lumière and Malespine⁹ showed that the phenomenon of reciprocal protection from one shock by another shock, or anaphylaxis, extended equally to histamine accidents, suggesting an analogy in the mechanism of the two types of shock. These and other experiments revealed that histamine could cause in animals anaphylactic-like reactions which closely resembled allergic reactions, and the assumption was made that the formation of a histamine-like substance constituted a part of every allergic reaction.

In 1909 Eustis advanced a theory that asthma was produced endogenously by the absorption of a powerful toxin probably from the intestinal tract, and he suggested that histidine, or its histamine derivative, was so absorbed. Duke expressed the similar belief that allergic reactions may be caused by the absorption of a histamine-like substance from the intestines. Koessler³ found, however, that histamine was rendered inert by its passage through the intestinal mucosa, and Wangenstein and Loucks²² reported that the amount of histamine absorbed from a strangulated intestinal loop was very small.

Received for publication, April 9, 1940.

Making practical application of his theory, Eustis in 1912 began using histamine in small doses in the treatment of asthma. He reported beneficial results but stated that following injections of histamine several of his patients developed hives or nettle rash. This point is of signal interest in light of the more recent investigations of McConnell⁹ and her associates who found that histamine, when applied to the skin of animals, or of man, promptly produced a wheal formation similar to that elicited by ordinary allergens in positive skin reactions. Lewis^{3, 9} also has observed, in a study of the response of the skin and its blood vessels to a variety of stimuli, a reaction characterized by (1) local dilatation of minute blood vessels, (2) increased permeability of vessel walls by direct action, and (3) widespread dilatation of the neighboring arterioles through the medium of local reflex mechanism. He has shown that a similar reaction in the skin is produced by histamine, and he attributes this reaction to the effect of some chemical substance already present in the cells and perhaps released by the stimulus of histamine. In view of the histamine-like action of this substance, Lewis designated it the H-substance.

Kline, Cohen, and Rudolph,⁹ in an investigation to determine the cellular reaction in allergic and nonallergic patients, found that specimens of tissue from allergic individuals excised after injections of allergens and histamine, and exposure to heat, cold, and scratching, showed almost complete infiltration by eosinophilic cells, whereas the reactions of nonallergic tissue were minimal. The histamine wheals in allergic persons were comparable histologically to those produced by allergens. This study indicates a similarity in the reactions of allergic individuals to ordinary allergens and to histamine.

It is apparent that the skin response to histamine application resembles that of allergen inoculation, and both in turn are similar to the wheal, erythema, and pruritus found in the lesion of urticaria or hives and in the bite or sting of bees.^{19, 24} Apparently histamine or Lewis' histamine-like "H-substance" is present in all tissue cells, and, when reflexly stimulated, it acts by means of, or in conjunction with, certain as yet undetermined other substances to produce vascular disturbances. On the basis of this theory, the vascular response, according to its location, may be productive of hay fever, asthma, nettle rash, migraine, etc., including urticaria and other skin lesions, as well as peptic ulcer. Because of the histamine-like nature of the H-substance it appears reasonable to assume that repeated, small, increasing doses of histamine might reduce the tendency to vascular reactions (1) by acting as an antigen in conjunction with the tissue cells, (2) by desensitization, (3) by altering the chemical nature of the H-substance, or (4) by increasing the output of adrenalin or histaminase in the circulation.

The therapeutic efficacy of histamine in allergic disorders has been demonstrated by various investigators, who have reported its favorable use in asthma, migraine, lupus, pruritus, eczema, hypersensitivity to cold and to heat, periodic edema of the hand and angioneurotic edema, purpura, and other conditions including urticaria.^{1-8, 10-13, 16, 18, 21, 25-27}

I. TREATMENT OF URTICARIA AND OTHER ALLERGIC DISORDERS

My use of histamine in 53 cases of urticaria and other skin lesions was stimulated by the report of Dzsinich,⁴ who in 1935 reported complete relief in 12 of 15 cases of bronchial asthma and in 3 cases of urticaria after treatment with small doses of histamine. Following in general his outline of treatment, dosage beginning with 0.00001 mg. of histamine and increasing to 0.1 mg. was used, dilutions being prepared from 1 c.c. ampoules containing 1 mg., of histamine dihydrochloride (1:1,000 solution).⁶ The initial dose was given intradermally and, as a rule, was 0.00001 mg. of histamine. If no reaction or aggravation of symptoms occurred following this dose, the same amount was injected subcutaneously forty-eight hours later, and the dose was increased according to schedule, doses being given not oftener than every other day. Any dose that appeared to aggravate symptoms was promptly reduced to one-tenth of the amount before increasing in accordance with schedule. (Dosages for treating urticaria and allied lesions in infants and children should be reduced in proportion.)

The solutions of histamine were prepared as follows.

1. Take 0.5 c.c. of the ampoule solution and dilute to 5 c.c. with normal saline. This gives 5 c.c. of solution containing 0.1 mg. of histamine per cubic centimeter.

2. Make subsequent dilutions similarly to obtain solutions containing 0.01 mg. per cubic centimeter, 0.001 mg. per cubic centimeter, and 0.0001 mg. per cubic centimeter, i.e., 0.5 c.c. of each immediately stronger solution, diluted to 5 c.c. with normal saline, will give the next weaker concentration, or one-tenth that of the respective "mother" solution. Solutions should be placed in appropriately labeled vials.

Each individual should first be tested with 0.1 c.c. from the vial labeled 0.0001 mg. per cubic centimeter, and the following considerations as to dosage should apply:

(a) Histamine-sensitive persons may experience headache, flushing of the face, and slight aggravation of symptoms. For this classification, the vial containing 0.0001 mg. per cubic centimeter should be further diluted (*0.5 c.c. diluted with normal saline to 5 c.c. and labeled 0.00001 mg. per cubic centimeter*), and graduated doses of 0.1 c.c., 0.3 c.c., 0.5 c.c., and 0.8 c.c. should be given from this dilution before proceeding with the routine schedule.

(b) All other cases should follow the schedule as given.

(c) For infants and children, test with 0.0000001 mg. or 0.000001 mg., making necessary dilutions similarly to those above.

Histamine was injected in most cases according to the following schedule, given at forty-eight-hour intervals for an average total of eighteen injections.

Vial 0.0001 mg./c.c.

0.1 c.c. (0.00001 mg.) intradermally

0.1 c.c. (0.00001 mg.) subcutaneously

0.3 c.c. (0.00003 mg.) subcutaneously

⁶The histamine preparation used in this study was Imido "Roche," manufactured by Hoffmann-La Roche, Inc., Nutley, N. J.

	0.5 c.c. (0.00005 mg.) subcutaneously
	0.8 c.c. (0.00008 mg.) subcutaneously
Vial 0.001 mg./c.c.	0.1 c.c. (0.0001 mg.) subcutaneously
	0.3 c.c. (0.0003 mg.) subcutaneously
	0.5 c.c. (0.0005 mg.) subcutaneously
	0.8 c.c. (0.0008 mg.) subcutaneously
Vial 0.01 mg./c.c.	0.1 c.c. (0.001 mg.) subcutaneously
	0.3 c.c. (0.003 mg.) subcutaneously
	0.5 c.c. (0.005 mg.) subcutaneously
	0.8 c.c. (0.008 mg.) subcutaneously
Vial 0.1 mg./c.c.	0.1 c.c. (0.01 mg.) subcutaneously
	0.3 c.c. (0.03 mg.) subcutaneously
	0.5 c.c. (0.05 mg.) subcutaneously
	0.8 c.c. (0.08 mg.) subcutaneously
	1.0 c.c. (0.1 mg.) subcutaneously

Patients notice a sensation of coolness in the skin following the first injection, and blanching of the skin is caused by peripheral capillary constriction. This is followed, within a few minutes, by diminution of edema, disappearance of wheals, and diminution of pruritic symptoms, with complete remission within a few hours, as a rule. However, symptoms return in about forty-eight hours after the first dose, although to a lesser extent. Subsequent doses apparently desensitize or increase the tolerance of patients; the result is complete and lasting remission of symptoms in the most responsive cases. The responsive patient suffering from urticaria with edema is comfortable after 3 doses, without recurrence of lesions.

My series of 53 patients with allergic skin with urticarial manifestations included 30 of urticaria alone, 22 of urticaria and angioneurotic edema, and one of pruritus without urticaria. Forty of these patients, or 75.5 per cent, were completely relieved by histamine without any additional therapy. Eleven persons, or 20.7 per cent, were improved, but other measures, including acid and enzymé (pancreas) administration, autohemotherapy, diet, removal of infection, etc., were necessary to complete relief. Two, or 3.8 per cent, were not benefited; one patient was aggravated by even minute doses of histamine, and the other had a shock reaction and was finally relieved by hysterectomy and autohemotherapy.

The duration of urticaria in these patients was from a few days to seven years, the average being four weeks to six months. The refractory period obtained through histamine therapy has lasted from twelve to twenty-two months. Only 3 patients have required additional therapy after twelve months, with ensuing benefit.

Other allergic syndromes in which histamine was employed included 5 cases of asthma, 2 of vasomotor rhinitis, 3 of infantile eczema, 3 of senile eczema, one of acute localized eczema of the forearms, three of atopic dermatitis, 3 of pollen dermatitis, 2 of pruritus ani, one of simple pruritus vulvae with edema, 2 of pruritus vulvae with leucorrhœa, one of atrophic arthritis of the wrist, one of edema of the penis from ant bite, and one of hydroarthrosis of the knee, intermittent type.

SIDE REACTIONS

While small doses of histamine favorably influence the allergic disorder, larger doses aggravate paroxysms of asthma and also increase the intensity of urticarial symptoms. Final doses should not exceed 0.1 mg. or 0.1 c.c. of the original 1:1,000 solution. Toxic symptoms include headache, dizziness, profound weakness, flushing of the face to cyanosis, irritability of the nervous system, and dyspnea. Epinephrine is the natural antagonist of histamine and should be given if a severe reaction develops in any abnormally sensitive person.

Evidence of reaction may follow injection within a few minutes to several hours. In certain individuals a slight chilliness was experienced within fifteen to thirty minutes after injections, followed by headache, flushing of the face, drowsiness, nervousness, shortness of breath, and extreme weakness, lasting from a few minutes to, in one case, four days, during which time the patient did not feel able to get out of bed. As Brown has suggested, certain individuals manifest abnormal reactions to histamine; evidently after shock reactions a refractory period may follow.

In cases showing more than a mild reaction, subsequent doses should be reduced by one-tenth the original amount, given as mentioned previously. As a rule, untoward reactions do not follow reduction in dosage; instead there is definite improvement in symptoms. This being the case, histamine may then be given in increasing doses without fear of untoward accident. It has been noted that while initial minute doses may cause marked reactions in some cases, the tolerance of these patients apparently can be increased until large doses (approximately 0.1 mg.) produce no discomfort.

However, in view of the occurrence of a limited number of so-called toxic manifestations from small doses (0.00001 mg.), I feel it necessary to issue a word of caution against the indiscriminate use of histamine. It is apparently contraindicated in the presence of cardiac pathology, particularly in cases of myocarditis or coronary sclerosis.

CASE REPORTS

These selected case reports are representative of the favorable response to histamine therapy in urticarial lesions:

CASE 1.—R. A., 26-year-old male, a manufacturer of overalls, had had severe urticaria and sinusitis following undulant fever seven years previously. There was a history of allergy in his father's family. Both tonsils and adenoids had been removed. He had been a heavy drinker and stated that he had had urticaria almost constantly, especially after drinking. Physical examination was essentially negative. He gave positive skin tests to corn meal, rice, rye, cocoa, milk, chicken, asparagus, yeast, hops, all shellfish, and grass pollen (spring group). Treatment was begun with grass pollen desensitization and elimination diet. Sinusitis was relieved, and hay fever symptoms subsided, but urticaria was not benefited. Histamine therapy was begun, and, disregarding food tests, a full diet was given to combat a drop in weight. Doses from 0.000001 mg. increased to 0.5 mg. according to the outline of Draitch. Results were complete relief of urticaria, restoration of weight, stabilization of nervous system, and increase of energy. Six months later the patient once again began to take large quantities of alcoholic beverages without recurrence of urticaria except for one day. This occurred following a week's spree and was relieved by 0.00001 mg. of histamine intradermally.

CASE 2.—T. L., 31-year-old male, a railroad office assistant, had edema of the glottis, with generalized urticaria. He gave positive tests for a variety of foods and other substances and was subject to tingling of hands, face, and lower lip, followed by choking cyanosis and general urticaria. The first attack followed influenza. Physical examination was negative. He was given Rowe's diet for six months; his symptoms disappeared, and he was retested. His diet was changed; remission of symptoms followed for four months. A recurrent attack was relieved with 0.000001 mg. of histamine. The patient was desensitized with histamine and put on a regular, unlimited diet. There was no recurrence after four months, and the patient is in excellent health.

CASE 3.—F. W. G., male, an electrician, had acute urticaria and rhinitis of several weeks' duration. The patient's entire back was covered with brawny edema in which hard, marblelike areas could be palpated. Edematous area approximated 1 inch in thickness. Extremities were covered with macular-type urticaria with intense pruritus. Nasal discharge was clear but resembled that of hay fever in character. Moderate bronchitis was present. Treatment with small increasing doses of histamine was begun; total number of doses was 19. This was followed immediately by a gradual diminution of edema and disappearance of lesions. Body was clear within ten days. The patient has had complete relief for the past twenty-two months.

The foregoing case is typical of the majority of cases of urticaria relieved by histamine.

CASE 4.—T. T., male infant, aged 5 months, had acute infantile eczema of face, arms, and legs, and of body on ventral surfaces. There was a family history of allergy; the father had hay fever. The mother's milk did not agree with the patient so he had been fed with cow's milk formula since he was 2 months old. *No change in formula was made.* Histamine therapy was begun with a dose of 0.0000001 mg.; total number of injections was 11. Eczema disappeared in approximately five weeks. There was no recurrence within seventeen months.

This case is representative of the use of histamine in infants; similar decreased doses should be employed in other such cases.

CASE 5.—W. R. G., female, had severe pruritus ani and a history of hay fever, backache, and urticaria. Local examination by a proctologist revealed no pathology. Histamine was used for relief of intense pruritus; no local treatment was given to the rectum or the anus. A total of 19 injections, ranging from 0.000001 mg. to 0.1 mg. per dose, was given. This was followed by complete relief of itching symptoms and discomfort for thirty days, after which time symptoms returned.

Although relief in this case apparently was only temporary, it indicates the therapeutic value of histamine in this type of condition.

CASE 6.—R. E. B., female, for three years had had hay fever, asthma, and eczema (dry type) over the entire body as well as a tendency to angioneurotic edema and urticaria. She gave positive skin reactions to various foods and other substances. Diets and desensitization therapy were given for twelve months, with only incomplete relief from hay fever and recurrences of urticaria and eczema. Then histamine was given in doses of 0.00001 mg. intradermally to 0.1 mg. subcutaneously. As a result the skin is clear and apparently normal for the first time, and the patient notices only a slight early morning cough. Further treatment for pollen sensitivity is being given at present following completion of histamine therapy.

CASE 7.—M. M., school girl, had had itching for four months. Examination revealed scabies-like lesions with furunculosis from scratching and infection. Scabicides were used without relief. Intradermal histamine injection relieved itching within forty-eight hours, and histamine desensitization treatment was given. The result was complete relief.

DISCUSSION

The favorable results obtained in this series of cases bear out the reported effectiveness of histamine therapy in allergic manifestations. Use of histamine

in accordance with the desensitization schedule described would seem to offer a simple and reliable means of relieving skin disorders, in particular those disorders occurring as the result of an allergic reaction to external or internal irritants.

The lasting relief of conditions like urticaria afforded by a single series of histamine injections suggests that the administration of histamine effects a kind of desensitization at least comparable in results to that achieved by more laborious and more costly specific desensitization procedures and that it is often of greater duration than that obtained by the latter.

Successful relief of allergic disorders by histamine as reported lends support to the theory that histamine or a histamine-like substance is produced in the body as an intermediate step in the body's reaction to the majority of, if not all, allergens. Its production may be illustrated schematically as follows:

Allergen → Sensitive body cells → Histamine (or histamine-like "H-substance") → Sensitive body tissue (vascular system) → Allergic reaction

Thus, on the basis of this hypothesis of the genesis of allergic reactions, when histamine is given according to a desensitization schedule, the sensitive body tissue, which formerly responded with a so-called allergic reaction to histamine produced by the impact of the allergenic substance on sensitive body cells, may be accustomed to histamine (desensitized) in such a way that it no longer reacts to the stimulus of allergen-produced histamine. The chain of events leading to the allergic manifestation is interrupted one step farther along than is the case with specific desensitization therapy where the response of sensitive body cells to the allergen itself is inhibited.

Obviously, the use of nonspecific histamine desensitization treatment has definite advantages which should appeal to both doctor and patient alike, since this method offers the doctor an immediate therapeutic means of relieving his patient, and also, in many cases, of obtaining a lasting remission, at a time when a search for specific irritants is exceedingly difficult. Of considerable importance is the fact that nonspecific desensitization therapy with histamine is considerably more economical than most specific desensitization procedures.

The side reactions reported are not uncommon to desensitization methods, and, while they illustrate the necessity for careful dosage and adequate supervision of the patient, they should not militate against the use of histamine any more than similar side effects deter the use of specific desensitization measures.

SUMMARY

Histamine dihydrochloride was employed parenterally in very small doses, increased from 0.00001 mg. to 0.1 mg. according to a definite desensitization schedule, in a series of 53 cases of urticarial-like allergic skin manifestations. Forty patients were completely relieved, 11 were improved, and only 2 were not benefited. Remission of symptoms obtained by histamine treatment has lasted for twelve to twenty-two months.

Twenty-eight other patients with various allergic syndromes were given histamine similarly, with a favorable response in the majority of instances.

These disorders, included infantile and senile eczema, rhinitis, pruritus ani, pruritus vulvae, atrophic arthritis, and edematous conditions.

Reactions of varying severity were experienced by some patients to injections of histamine. Reduction of the dosage in most cases effected control of the reaction and permitted effective continuation of therapy. However, careful administration of histamine is essential; its use is apparently contraindicated in patients with certain cardiac disorders.

CONCLUSIONS

Complete remission of symptoms may be obtained in many cases of urticaria by the injection of minute doses of histamine dihydrochloride, increased regularly by small amounts in accordance with a desensitization schedule.

The similar use of histamine may be beneficial in other allergic skin conditions, particularly those evidenced by pruritus, edema, and exudation.

A word of caution is indicated with regard to indiscriminate histamine therapy.

II. TREATMENT OF GASTRODUODENAL ULCERATION

The etiology of peptic ulcer is not yet definitely known, and various theories have been promulgated to account for its occurrence. Some of these hypotheses hold that an allergic reaction is at the etiologic base of many cases of gastroduodenal ulceration. The possible mechanism of such a reaction, involving liberation of a histamine-like substance and an ensuing vascular response which may eventuate in peptic ulcer formation, has been discussed in Part I.

Since desensitization with histamine was effective in correcting allergic manifestations such as urticaria and eczema, it was decided to employ a similar desensitization schedule in certain cases of peptic ulcer, on the assumption that peptic ulcer is caused by the influence of some allergen or allergens. This decision was aided by the fact that several patients treated for cutaneous allergic disorders simultaneously experienced relief of ulcer symptoms.

Eleven cases of peptic ulcer syndromes, in several of which the history suggested that allergy played a causative role, were given histamine injections, using the 1:1,000 solution of histamine dihydrochloride. The same schedule as for urticaria was followed—0.00001 mg. intradermally increasing to 0.1 mg. in successive subcutaneous doses at forty-eight-hour intervals. A twelfth patient with gastric carcinoma was also given histamine for its favorable effect on pain, appetite, etc. The brief case reports which follow illustrate the response of these 12 patients to histamine therapy.

CASE REPORTS

CASE 1.—L. D. E., male, aged 12 years, was sent in for an allergy examination to determine the cause of rhinitis. He had had an appendectomy two years previously, asthma the summer before, and head cold and sinusitis for the past few weeks. There was a history of allergy in the family and hay fever in the father. During examination the patient complained of pain in abdomen with marked tenderness over epigastrium. X-ray examination revealed characteristic ulcer deformity. Belladonna administration and a modified Sippy diet were begun. On the first day of his hospital stay an urticarial rash was noted over the abdomen, which itched intensely. A dose of 0.00001 mg. of histamine was given intradermally for the urticaria, and both urticaria and epigastric pain were relieved within twenty-four hours; previously it had been necessary to administer $\frac{1}{8}$ gr. of morphine for

relief. Pain returned the third day, and histamine was again given, with astonishing relief. The patient was kept in the hospital for ten days on a modified Sippy diet and belladonna, but also received histamine according to the desensitization schedule every other day, with no recurrence of pain or other discomfort. After a six weeks' diet therapy x-ray showed an apparently normal intestine. There has been no recurrence within eighteen months.

Attention is called to the relief of urticaria and pain in this case.

CASE 2.—Negro, male, aged 50 years or more, a day laborer, complained of pain characteristic of duodenal ulcer. X-ray examination showed definite deformity of the cap; this deformity was not influenced by atropine. Sippy diet, belladonna, and sedatives were given for two weeks; the patient remained in bed for one week. This treatment did not bring about relief of pain and discomfort. Since it was evident that his condition was not improving and since it was difficult to keep him on a diet, surgery was considered. First, however, in view of the good results in Case 1, 0.0001 mg. of histamine was injected intradermally. The patient noticed almost immediately that his sensation of fullness was diminished, and he felt more comfortable and remained so for forty-eight hours; then symptoms returned. Subsequent small doses of histamine, increased every other day for approximately 20 doses to 0.1 mg., brought about apparently complete relief. Twelve months later, working twelve hours daily at hard manual labor and thinking very little about diet, this man is symptom-free.

Attention is called to the fact that the patient continued to experience fullness, soreness, acute pain, and distress until after histamine therapy was begun. From that point on there was a distinct diminution in his symptoms, with relative comfort after the fourth injection.

CASE 3.—J. L. P., male, aged 60 years, a railroad employee, had black tarry stools, extreme weakness, general gastric upset, and distress for one week before consulting me. I had attended him for perforations in the duodenum ten years previously, at which time an operation was performed which involved the simple closure of two ulcers with uneventful recovery. The patient was put to bed under treatment with an oral proprietary preparation, belladonna, and modified Sippy diet for one week. After stools had cleared, diet therapy was continued. X-ray examination showed constant deformity of ulcer, slight narrowing of pylorus, and retention after six hours. Medical treatment was continued, but as this did not give patient appreciable relief, gastroenterostomy was advised and declined. Mr. P. was convinced that he had a malignancy and would not listen to any suggestion of surgery, despite discomfort. He was finally persuaded to try histamine therapy, keeping a daily record of his sensations and symptoms following each dose. The following are excerpts from the record:

"5/11/38 At one-thirty P.M., after having taken a shot at eleven A.M., am feeling fairly comfortable in my stomach.

"5/13 Had no unpleasant feeling in my stomach after lunch today. Lay down for a couple of hours, got up feeling better than for a couple of weeks.

"5/15 Did not wake with pain last night as usual.

"5/17 Had real severe pain last night but ate a canned pear which I think caused the trouble.

"5/19 I am feeling lots better after each shot now, only I am growing a bit weak.

"After the fourth shot the only change I notice is that I am feeling better each day. . . . I did not keep further daily data as the only effects I felt were that I was improving daily. I would have turned this in sooner but was waiting to see what the results would be and to see if the shots had made a complete cure, which I am convinced they have, as I have had absolutely no pain since the fourth shot. My appetite is good, and I eat practically anything I want, but I try not to eat too much. Have lost only one day from work since the thirteenth of August and this is the twenty-eighth of September."

These results indicate the evident relief with histamine, without observation of dietary restrictions. Several weeks later, however, x-ray examination indi-

cated a defect which, I believe, may be the result of adhesions following previous perforation, since the patient is symptom-free.

CASE 4.—B. A., white male, aged 37 years, complained of duodenal ulcer. He stated that he felt exactly as he did prior to his last perforation—he had been operated upon twice previously with simple closure of perforations. Physical examination was essentially negative except for ulcerlike tenderness and marked undernourishment. There was a history of two attacks of asthma in 1934, with occasional difficulty in breathing and nasal obstruction. Since the patient required considerable building up for operation and since there was no indication of pyloric obstruction, he was put on an oral proprietary preparation, belladonna, and a modified Sippy diet, with occasional sedatives. After three weeks he did not improve subjectively and histamine therapy was initiated, beginning with 0.00001 mg. intradermally. There was a noticeable improvement in comfort during the next forty-eight hours. Histamine injections were continued, with relief of symptoms, and the patient was discharged some three weeks later, apparently well and symptom-free. After a short interval, during which time no injections were given, symptoms returned, and a posterior gastroenterostomy was performed. The stomach was normal and the duodenum showed two healed, old ulcers, but no evidence of induration of recent ulcer. Adhesions in the upper gastrointestinal tract were corrected. Following the operation recovery was uneventful except for hicough which responded to treatment, but convalescence was delayed by the patient's mental state. He would not take nourishment, complained of every trifle, and, in general, was very hard to manage. Since such notable improvement had resulted from histamine prior to operation, it was again employed in an attempt to aid in recovery. Injections of small doses brought about a decided change for the better: the patient's appetite returned, his attention to personal appearance improved, and he wanted to sit up and get out of bed. Saline injections were given for one week as a control procedure and symptoms returned, to be relieved by further histamine therapy.

In this case the preoperative use of histamine enabled us to build up the patient sufficiently to stand operation, and its postoperative use was of benefit in his recovery. Gastroenterostomy described above was performed in September, 1938; in April, 1939, the patient complained of soreness and distress in epigastrium. He was again given 13 injections of histamine, following which his symptoms subsided and he gained 6 pounds. The patient is apparently well at present.

CASE 5.—H. D., male, aged 40 years, complained of pain in stomach, gas, vomiting, blood in stools, and fullness after meals. Physical examination revealed an undernourished male, with tenderness in epigastrium. X-ray examination showed normal esophagus and stomach; a large crater on posterior wall of the duodenal bulb, a wide inflammatory ring about ulcer, and a diverticulum on the descending portion of duodenum. The patient was given 0.00001 mg. of histamine and on the following day felt better than he had for three weeks previous. A bland diet was given without alkali neutralization or other medication. After two injections of histamine the patient was discharged from the hospital under the care of his physician who continued with a regular schedule for histamine injections. He improved clinically from the first injection. Two months after histamine therapy was begun, x-ray examination showed a fluoroscopically normal stomach, with no hypersecretion; moderate constant deformity of duodenal bulb, but no visible niche; no retention at six hours, but moderate degree of hypermotility. His physician reports clinical relief has been maintained to date.

CASE 6.—E. McK., female, aged 41 years, had pain in epigastrium and distress characteristic of ulcer. She had been treated for peptic ulcer since October, 1938, at which time she had a hemorrhage. Two years previously a gastroenterostomy had been done. Physical examination was essentially negative except for tenderness in epigastrium to left of old laparotomy scar. X-ray examination on admission revealed evidence of a stomal ulcer with

a well-functioning gastroenterostomy. After a blood transfusion the patient was put on histamine therapy and a bland diet, with apparent clinical improvement. She was given injections at the hospital for ten days and then discharged; she received subsequent injections at the office. She was apparently symptom-free one month after beginning histamine therapy, and although she had slight retention at six hours, the roentgenologist reported that no stomal ulcer could be demonstrated. After a remission of several weeks, the patient again complained of distress in epigastrium. X-ray examination check showed a well-functioning gastroenterostomy; a small niche was observable at the stoma. Barium did not pass through the duodenum, there being a 10 per cent retention at six hours; the remainder of the barium passed normally into the cecum. The patient was advised to re-enter the hospital for observation, but a bed was unavailable at the time and she has since failed to appear for treatment.

In this case definite clinical improvement was noted, particularly subjective improvement, regardless of the x-ray findings. The patient was almost deaf, and it was exceedingly difficult to obtain information from her; also her mental state was not the most favorable for this type of cooperative study.

CASE 7.—C. B. A., female, aged 48 years, complained of pain in the right upper quadrant and back, with hematemesis, indigestion, fullness in epigastrium, headache, sinusitis, nervousness, and hot flushes. General examination revealed only tenderness over the gall bladder on deep pressure; symptoms and history were suggestive of gall bladder disease or peptic ulcer. X-ray examination showed good gall-bladder shadows, with no evidence of calculi; in gastrointestinal series the stomach appeared normal, with normal peristalsis and well-filled duodenal bulb. There was a minimal deformity of the duodenal cap, without definite niche. The patient had a chronic duodenal ulcer and was put on a bland diet without antacid medication and allowed to be ambulant. A daily record of experiences following histamine injections was kept. After the sixth dose she began to feel comfortable and did not spit up further blood. She received from 0.00001 mg. to 0.1 mg. of histamine in 17 injections.

I was unable to again x-ray this patient after the period of histamine injections, so no definite conclusion can be made of the degree of healing of her ulcer which may have taken place. Following the sixth injection, however, she was clinically free of symptoms for an indefinite period of time, slight symptoms recurring after twelve months.

CASE 8.—F. L. E., male, aged 31 years, a painter, had pain in his right side, nagging in character, with nausea, occasional vomiting, constipation, and nervous indigestion for six years. Physical examination was essentially negative except for poorly kept teeth and pyorrhea. X-ray examination after barium enema showed no evidence of pathology. In gastrointestinal series the chest and esophagus were fluoroscopically normal, there were considerable hypersecretion in stomach, spastic pylorus, marked deformity of duodenal bulb, and definite niche; the second portion of the duodenum was redundant. There was 20 per cent retention in stomach at six hours, but progress of the barium was normal beyond the stomach. The patient was put on a bland diet, and injections of histamine were begun. Immediately following the first dose (within three to four hours), he experienced definite relief of sensation of fullness, gas, and pain in the side; his appetite improved, and he felt generally better and stronger. Despite a complete series of histamine injections he still continued to experience some discomfort in his side. A confirmatory x-ray examination was made; it showed no abnormality in esophagus or stomach, but revealed a large ulcer pocket just distal to the pyloric sphincter. Retention in the stomach with considerable spasm about the pylorus was also noted.

In this case a combination of aluminum hydroxide, diet, rest, and histamine would probably have effected a more definite response. Subjectively, this

patient was the only one of those with known ulcer who did not respond satisfactorily to histamine alone. However, both x-ray and gastric analysis indicated improvement.

CASE 9.—J. M. G., male, aged 41 years, has since 1929 suffered from gastrointestinal symptoms suggestive of duodenal ulcer. He has taken soda, mineral oil, etc., for distention, gas, and discomfort most of his life. An x-ray examination in 1936 showed that he had an ulcer. A second x-ray examination in 1937, by a different laboratory, did not demonstrate an ulcer. He was given 14 injections of histamine (0.00001 mg. to 0.01 mg.) at intervals of every other day; this therapy resulted in remission of symptoms for seven months, after which time he returned for further prophylactic injections, stating that for this period he had been symptom-free.

CASE 10.—O. G. C., male, aged 46 years, was x-rayed in 1937 and told he had an ulcerated stomach. An x-ray examination in 1939 revealed a normal stomach and upper intestinal tract, but definite colitis and symptoms of duodenal ulcer. Because his teeth and gums were poor, his teeth were removed. Histamine injections were given before and during the removal of teeth with lasting abatement of symptoms. The discomfort was relieved immediately and has not returned to date.

CASE 11.—W. I. G., male, aged 40 years, was previously x-rayed, but no definite evidence of ulcer was found. He presented a history of indigestion, gas distention, nausea, gastric upsets, constipation, relief from soda, etc. A series of histamine injections afforded him remission of symptoms for several months. At present, after a nine months' symptom-free period, he is again experiencing some discomfort.

CASE 12.—J. W., aged 39 years, was admitted to service on Aug. 23, 1939, with diagnosis of gastric ulcer. He was discharged and re-admitted on Sept. 20, 1939. He gave a history of syphilitic infection fifteen years previously with requisite treatment. X-ray examination revealed advanced infiltration of carcinoma in cardia and lower esophagus. The patient was, therefore, not a proper subject for histamine therapy, but histamine was given in an attempt to improve his appetite, and to determine what effect, if any, it might have on his feeling of well being. A noticeable improvement in comfort, in appetite, and in mental outlook resulted. The patient became hungry and had no difficulty with his food. His general condition was also improved considerably prior to his departure to a clinic for surgical attention.

DISCUSSION

It may be very significant from the standpoint of etiology of peptic ulcer that the same dosage schedule of histamine injections employed successfully in treating urticaria and other skin lesions is effective in affording remission of ulcer symptoms. An allergic reaction has been proved to underlie the urticarial disorders described in Part I, and reasoning by analogy one may assume that cases of peptic ulcer responsive to histamine are similarly caused and perpetuated.

Of course, it is not justifiable to assume on the basis of results in this small initial series that all cases of peptic ulcer have an etiologic background of allergy; in fact, the effectiveness of histamine may conceivably be that of the substance per se, rather than of its desensitizing influence against external or internal irritants. However, there is sufficient evidence of improvement of ulcer symptoms in individuals of an allergic diathesis after injections of histamine to warrant the assertion that allergy plays a certain causative role. This assumption derives further support from the observation of simultaneous relief of allergic skin disorders in patients whose peptic ulcer symptoms are also benefited.

Psychic factors should be considered to a certain extent in evaluating the efficacy of this type of therapy. However, that they probably play a minor role is evident from the finding that in at least one case, symptoms which had been relieved by histamine injections returned when saline solution was substituted for the histamine; when histamine therapy was reinstituted, the symptoms once more disappeared.

The small doses of histamine injected did not stimulate gastric acid secretion, as demonstrated by gastric analyses. This finding is of importance in view of the fact that peptic ulcer is invariably aggravated by increased acid flow. An effective therapeutic method should have no stimulating influence on acid production, and histamine therapy in the dosage employed apparently satisfies this criterion.

SUMMARY

Eight patients with peptic ulcer syndromes and demonstrable ulcers were treated with a bland diet, supplemented by injections of histamine according to a desensitization schedule, without any attempt at acid neutralization. Similar treatment was given in three other patients with similar symptom syndromes but without demonstrable evidence of ulcer. A twelfth patient with advanced carcinoma of the esophagus and stomach was also given a series of histamine injections during his hospitalization period.

Subjectively, the ulcer patients experienced relief of symptoms, in most instances following the fourth histamine injection, and they were able to enjoy a fuller diet than the routine in similar cases. There was a return of a sensation of well-being in the person with cancer, with increase in appetite as well as in comfort. Remission of symptoms in duodenal ulcer syndromes without demonstrable lesions was apparently dependent on the total number of injections and the amount of histamine given.

Studies of gastric function did not demonstrate hypersecretion of acid from small doses of histamine; rather, there appeared to be some inhibition of secretory activity, and in one case actual lowering of the acid curve.

X-ray studies of gastric functional activity and the regression of previously demonstrated niches in several cases confirmed subjective evidence of improvement or healing of ulcer lesions.

No marked reactions to injection of histamine, but occasional headache and generalized aching, with a feeling of weakness, were experienced by some patients.

CONCLUSIONS

It would appear from the results obtained and the observations made in this small series of cases that repeated injections of small amounts of histamine, in increasing doses, can well be used to augment the more recognized treatment of peptic ulcer, supplementing diet, rest, and acid neutralization.

It would also appear that the use of histamine desensitization therapy in patients with ulcer symptom syndromes, but without demonstrable ulcers, can afford these patients a remission of symptoms.

The favorable response of patients with peptic ulcer syndromes to histamine in small increasing doses would indicate an allergic basis for the develop-

ment or maintenance of the syndrome in these cases. The response is similar, in respect to the type of therapy involved, to that observed in cases of urticaria and other skin lesions of a proved allergic etiology.

From a consideration of the various factors involved, it would appear that the use of histamine in peptic ulcer has a certain place, particularly in those patients who are of the so-called allergic diathesis type and manifest other symptoms of an allergic character.

Further investigation of the histamine therapy of peptic ulcer is recommended.

Acknowledgment is hereby made to Dr. Alvin E. Siegel and Dr. B. S. Gostin for the use of cases from the Medical Services of the Macon Hospital and for their interest and assistance.

CLINICAL CHEMISTRY

THE ACID-BASE BALANCE IN THE PLASMA AND BLOOD CELLS OF NORMAL NONPREGNANT, PREGNANT, AND PUERPERAL WOMEN*

FRED W. OBERST,† Ph.D., LEXINGTON, KY., AND E. D. PLASS, M.D.
IOWA CITY, IOWA

THE acid-base equilibrium in the plasma of normal pregnant women has been intensively studied by many investigators, but there is still some disagreement concerning the extent and significance of the variations involved. Oard and Peters,¹ Muntwyler, Limbach, Bill, and Myers,² Kydd,³ Kydd, Oard, and Peters,⁴ Myers, Muntwyler, and Bill,⁵ and Nee, Mull, Muntwyler, and Myers⁶ have recently reviewed the literature and have made excellent contributions toward the solution of this complex problem. It is generally agreed that during gestation there is a reduction in the carbon dioxide content and in the protein percentage of the plasma, which is associated with a comparable diminution in the total base, but there is still some difference of opinion as to whether these changes affect the hydrogen-ion concentration. The present study was designed to investigate the plasma and whole blood and by calculation to determine alterations in the blood cells.

MATERIAL

Complete studies were made on (a) ten normal nonpregnant women of the childbearing age (nurses and ambulatory patients with minor afflictions that ordinarily would not disturb the acid-base or the water balance), (b) ten primigravidas and ten multigravidas who were in the third trimester of pregnancy and who showed no signs or symptoms of disease, and (c) ten normal postpartum women who were tested seven to nine days after delivery. All individuals received the regular (mixed) hospital diet.

METHODS AND CALCULATIONS

A portion of the blood was drawn under anaerobic conditions into tubes containing dry sodium oxalate and oil and was analyzed for carbon dioxide content and capacity, oxygen content and capacity, chlorides, phosphates, cell volume, and water. A second portion, similarly treated, was centrifuged under oil, and the supernatant plasma was used for determining the carbon dioxide content and capacity, hydrogen-ion concentration, total protein, nonprotein nitrogen, chlorides, phosphates, and water. The final portion was collected in a clean dry tube and allowed to clot, the serum being used for analyses of sodium, calcium, magnesium, and sulfates. Potassium was determined on the solid

†Biologic chemist at the United States Public Health Service Hospital, Lexington.

Received for publication, February 14, 1940.

residues obtained when whole blood and plasma were dried to constant weight in the water content determinations, as previously described.⁷

The concentrations of the various blood cell constituents were calculated from determined data on the concentrations in whole blood and plasma and on the cell volumes, using the generalized formula:

$$\text{Concentration in the whole blood} = \frac{\text{Concentration in the plasma} \times \text{plasma volume} + \frac{X \times \text{cell volume}}{100}}{100}, \text{ where } X \text{ is the concentration in the cells.}$$

The various plasma and cell constituents are reported in terms of milliequivalents.* The total acid represents the summation of the anions bound with the basic elements. Total acid equals $[\text{proteinate}]^- + [\text{HCO}_3]^- + [\text{Cl}]^- + [(\text{HPO}_4)^{-}] + (\text{H}_2\text{PO}_4)^{-}] + [\text{SO}_4]^{-}$. On the other hand, the total base equals $[\text{Na}]^+ + [\text{K}]^+ + [\text{Ca}]^{++} + [\text{Mg}]^{++}$, which represents the sum of the cations.

Cell volumes were determined by using Plass and Rourke sedimentation tubes† and rotating them at 3,000 r.p.m. for thirty minutes.

Oxygen and carbon dioxide contents and capacities were determined by the manometric method of Van Slyke and Neill,⁸ using the gas apparatus and technique of Van Slyke.⁹ Factors of 0.1 and 0.5 volume per cent were subtracted from the oxygen content and capacity, respectively, for the dissolved and the free oxygen. If we assume that one molecule of oxygen combines with one molecule of hemoglobin, the corrected oxygen capacity divided by 2.24 gives the millimols of hemoglobin.

The hydrogen-ion concentration of the plasma was determined by a K-type potentiometer with a quinhydrone microelectrode similar to that described by Cullen.¹⁰

Volumes per cent of carbon dioxide were converted into milliequivalents present as bicarbonate by the following equation^{11, 12}:

$$[\text{BHCO}_3] = [\text{CO}_2] - \frac{[\text{CO}_2]}{10^{\text{pH} - \text{pK}^1} + 1}$$

in which $[\text{CO}_2]$ represents the millimolar concentration of total CO_2 or $\frac{\text{Volume per cent } \text{CO}_2 \times 0.01976}{0.044}$. pK^1 values of 6.10 and 6.13 were used for

plasma and whole blood, respectively. The factor $\frac{[\text{CO}_2]}{10^{\text{pH} - 6.10} + 1}$ represents the concentration of free carbonic acid in the plasma.

The alkali reserve was calculated from the volume per cent carbon-dioxide combining power by means of the formula used to determine the amount of BHCO_3 .

Carbon dioxide tension was calculated from the carbonic acid concentration in the plasma by the following formula:

$$p - \text{CO}_2 \text{ mm.} = \frac{[\text{H}_2\text{CO}_3]_s}{0.0327}$$

*A milliequivalent, or millimol (mEq. or mM), of a given constituent represents $\frac{1}{1000}$ part of its hydrogen equivalent or of its molecular weight, respectively, per kilogram of water. For example, 1.0 mEq. of sodium equals $\frac{1}{1000}$ of its atomic weight divided by 1.008 (its hydrogen equivalent), or $\frac{23}{1,000} \div 1.008 = 0.023$.

†Manufactured by Macalaster, Bicknell Co., 40 Wendell St., Cambridge, Mass.

The Folin-Wu method¹³ was used to determine the nonprotein nitrogen in plasma and whole blood.

The total nitrogen of plasma was determined by the micro-Kjeldahl method.¹⁴ After the nonprotein nitrogen was subtracted, the protein nitrogen was multiplied by the factor 6.25, to obtain the total protein percentage, which was converted into milliequivalents of base combined with protein, [BP], by the formula of Peters, Wakeman, Eisenman, and Lee,¹⁵ $[BP] = 1.072 P$ ($pH - 5.04$), in which an albumin-globulin ratio of 1.8 was assumed.

The Wilson and Ball procedure for chlorides in whole blood and plasma was employed.¹⁶ The milligrams per cent of sodium chloride divided by 5.85 represent the milliequivalents of chlorides in 1,000 c.e.

Inorganic phosphorus was determined by the method of Youngburg and Youngburg.¹⁷ The milligrams per cent of phosphorus was reduced to milliequivalents of $[HPO_4]^{--} + [H_2PO_4]^-$ per liter by the factor $\frac{18}{31.04}$, accepting Henderson's¹⁸ estimate of the proportion of primary and secondary phosphates.

In the sulfate determinations the benzidine sulfate was prepared according to Wakefield,¹⁹ but instead of proceeding to a colorimetric comparison, a titrimetric method was employed, using 0.02 normal sodium hydroxide with phenol red as the indicator. Assuming that each atom of sulfur combines with two equivalents of monovalent base, 1 mg. per cent of sulfate is equivalent to 0.208 mEq. of combined base.

The specific gravities were determined by weighing 2.0 c.e. of plasma or whole blood in a 25 c.e. silica crucible. The water content was obtained by drying the specimen at 105° C. to constant weight.

Potassium was determined on the dried material remaining in the crucible, which was treated with one or two drops of concentrated sulfuric acid and ashed overnight at a low heat in an electric muffle. The ash was dissolved in a few drops of dilute hydrochloric acid and water. The solution obtained from the plasma specimen was transferred to a 15 c.e. centrifuge tube and evaporated to dryness, while that from the whole blood was transferred to a 15 c.e. graduated centrifuge tube, made up to 10 c.e. with water, and centrifuged to separate the insoluble iron oxide; an aliquot portion of the clear supernatant solution was transferred to another centrifuge tube and evaporated to dryness. The residues from the serum and whole blood were analyzed for potassium by the method of Shohl and Bennett.²⁰ One milligram per cent of potassium is equivalent to $\frac{1}{3.91}$, or 0.256 mEq. per liter.

The serum sodium was determined by the zinc uranyl acetate technique of Salit.²¹ The direct method previously described by one of us²² was used to determine the cell sodium, the concentration values of which are recorded.

One milligram per cent of sodium is equivalent to $\frac{1}{23}$, or 0.0434 mEq. per liter.

Calcium was determined by the Clark and Collip²³ modification of the Kramer-Tisdall procedure.²⁴ One milligram per cent of calcium is equivalent to $2 \times \frac{1}{4.0}$, or 0.5 mEq. per liter.

The method of Denis²⁵ was employed for the determination of magnesium. One milligram per cent of magnesium is equivalent to $2 \times \frac{1}{2.43}$, or 0.819 mEq. per liter.

The base bound by hemoglobin, or base protein, $[\text{BP}]_c$, was calculated according to the equation of Van Slyke, Wu, and McLean:²⁶

$$[\text{BP}]_c = 3.35 [\text{Hb}]_c (\text{pH}_c - 6.74) + [\text{O}_2]_c (0.25 \text{ pH}_c - 1.18)$$

where $[\text{Hb}]_c$ represents millimols of hemoglobin per kilogram of water; $[\text{O}_2]_c$, the millimols of oxygen per kilogram of water, and pH_c , the hydrogen-ion concentration within the cells as estimated from a graph using plasma pH data.²⁵ The values thus obtained may not represent the base actually bound by the hemoglobin in human blood, since the equation was derived from data on horse hemoglobin, but they undoubtedly have some value for comparative purposes.

RESULTS

The average values for the various constituents (Table I), except those for the pH, are in accord with the reports of previous investigators.¹⁻⁶ The average pH value is the same in the pregnant women as in the nonpregnant, thus confirming the observations of Kydd, Oard, and Peters,⁴ and others. The total acid and the total base are diminished approximately 5.5 mEq. during late pregnancy but return to the nonpregnant level within seven to nine days after delivery. Reductions of the bicarbonate and of the proteinate ions account chiefly for the decrease in total acid, while the lowered sodium explains the reduced total base, which is associated with a lowered alkali reserve. The average values for carbon dioxide tension and for carbonic acid, as calculated from the total carbon dioxide content of the plasma, are slightly reduced in late pregnancy but return to normal shortly after delivery.

Since all values recorded for the blood cells (Table II) have been calculated from the analyses of plasma or serum and of whole blood, and from hematocrit determinations, it is obvious that they are subject to undue variations as the result of a possible summation of analytic errors. Average values for cell chloride and bicarbonate in the nonpregnant group agree with those reported by Hastings, Sendroy, McIntosh, and Van Slyke,¹² but they are lower in the groups of women in late pregnancy; this confirms the observations of Muntwyler, Myers, and Way.²⁸ The cell proteinates and phosphates show no significant variations in the different groups. During pregnancy the total acids in the cells are approximately 7.6 mEq. per liter below the nonpregnant level, and by the seventh to the ninth days post partum they have only partially returned to normal, being still 4.0 mEq. under the nonpregnant average.

The cell potassium, which represents most of the total base in the cells, is slightly elevated in the pregnant groups, the rise being associated with an increased hemoglobin content per kilogram of water, as previously reported.¹ During the early puerperium the cell potassium rises still higher, and there is no indication as to when it returns to normal. Values for the sodium content of the cells are available only for the pregnant groups, and consequently no comparison can be attempted. The alkali reserve is increased slightly in the

cells during gestation but is decreased in the plasma. After delivery both serum potassium and plasma alkali reserve return promptly to the normal non-pregnant level, in spite of the persistent elevation of the cell potassium.

DISCUSSION

The recorded pregnancy changes in the various plasma constituents confirm the observations of previous investigators and require no comment.

During pregnancy the diffusible constituents of the blood cells vary generally with the alterations in the plasma to maintain a Donnan type of equilibrium. The total base of the cells is not influenced by the reduction in the total base of the plasma but actually rises slightly because it consists largely of non-diffusible potassium, which is closely associated with the equally fixed hemoglobin. This situation probably explains the increased alkali reserve of the cells. The amount of base bound with hemoglobin to form a proteinate is governed by the pH and the carbon dioxide content of the blood. In general, the variations in the acid-base balance of the cells are due directly to alterations in the concentrations of the diffusible constituents of the plasma.

An interpretation of the acid-base balance in pregnant and puerperal women has been presented in a previous communication dealing with pulmonary ventilation.²⁹

SUMMARY

1. A detailed study of the acid-base equilibrium of the plasma and cells in normal ten nonpregnant, twenty pregnant, and ten puerperal women is reported.
2. The reduction of the total acid constituents of the plasma, which occurs during pregnancy, is balanced by a corresponding reduction in the total base, with both factors returning to normal early in the puerperium.
3. The pH of the plasma remains at the normal nonpregnant level during pregnancy and early puerperium.
4. The free carbonic acid and the carbon dioxide tension of the plasma fall slightly in late pregnancy but return to the nonpregnant level shortly after delivery.
5. The total acid constituents in the cells are slightly diminished in late pregnancy but return to normal within nine days after delivery.
6. The potassium concentration in the cells, which is increased in late pregnancy, shows a further rise during the early puerperium.
7. The alkali reserve of the cells is increased during pregnancy but falls to the nonpregnant level within a few days after confinement.

THE MAGNESIUM CONTENT OF THE BLOOD SERUM AND URINE*

MITCHELL BERNSTEIN, M.D., F.A.C.P., AND SAMUEL SIMKINS, M.D.
PHILADELPHIA, PA.

BECAUSE of the increasing importance of magnesium in the field of cardiovascular-renal disease and because of the relative dearth of data in the literature, the present investigation of the magnesium content of the blood serum and urine was undertaken.

The patients studied comprised 201 consecutive medical ward cases, divided almost equally between both sexes. A total of 325 blood serum determinations was performed. Insofar as could be determined the patients had no disturbance of mineral metabolism. In general, a fasting blood magnesium test was made although it has been shown that no noticeable difference exists in the magnesium content of the blood before and after meals.¹ The method employed for the determination of magnesium was the modification of the Titan yellow dye method recently perfected by Haury,² a method so essentially simple and dependable that it ought to mark a great step forward in the clinical investigation of magnesium metabolism.

The statement is seen repeatedly in the literature that the amount of blood magnesium is remarkably constant, varies within very narrow limits only, and is practically uninfluenced by pathologic processes.^{3, 4} Yet a careful perusal of the literature disclosed very marked divergences in the recorded data.

The patients were divided into a noncardiac group with a wide miscellany of diseases, a cardiac group, and a nephritic group. The combined cardiac and noncardiac group totaled 197 patients in whom 312 blood serum magnesium tests were performed. The average magnesium value was 2.1 mg. per cent which agreed fairly well with the results of Beecher⁵ (1.8 to 2.3), Bomskov⁶ (1.7 to 2.6), Velluz and Velluz⁷ (2.00) (1.62 to 2.40), Brookfield⁸ (2.04) (1.89 to 2.19), Cope⁹ (2.06) (1.82 to 2.63), and Walker and Walker¹⁰ (1.5 to 2.9), but was considerably below the values obtained by Greenberg and others¹¹ (2.74) (2.0 to 3.6), Briggs¹² (2.23 to 2.50), Wacker and Fabrig¹³ (2.4) (2.03 to 2.97), Denis¹⁴ (1.6 to 3.5), Cohen¹⁵ (2.56) (2.09 to 2.74), Marriott and Howland¹⁶ (2.2 to 3.5), Kramer and Tisdall¹⁷ (2.3 to 4.0), Watchorn and McCance¹⁸ (2.3 to 2.65), Watchorn¹⁹ (2.2 to 2.6), and McCance and Watchorn²⁰ (2.00 to 4.05). A noteworthy feature is the marked individual variations we found (1.23 to 3.54) in support of the findings of Greenberg and co-workers.¹¹ Evidence of the serum magnesium does not vary within such narrow limits as was hitherto supposed.

*From the Medical Service of Dr. Mitchell Bernstein, Jewish Hospital, Philadelphia.
Read before the Jefferson Society for Clinical Investigation, Jefferson Medical College, Philadelphia, December 21, 1939.
Received for publication, November 7, 1939.

NONCARDIAC GROUP

The noncardiac group included 94 patients in whom 138 magnesium tests were performed. The average serum magnesium was 2.12, with extremes of 1.37 to 3.11. A division of this group into smaller groups of patients with definite diseases (such as pneumonia, irritable colon, cholelithiasis, bronchial asthma) disclosed no great variations from the general average. The pregnancy group (comprising 4 cases) tended to show somewhat lower values in support of the findings of Watchorn and McCance.¹⁸ The miscellaneous section comprised a great variety of diseases, including erysipelas, Hodgkin's disease, scleroderma, Henoch's purpura, bronchiectasis, psoriasis, thromboangiitis obliterans, ulcerative colitis, and chronic lymphatic leucemia.

TABLE I
BLOOD SERUM MAGNESIUM VALUES

DIAGNOSIS	NO. OF PATIENTS	NO. OF TESTS	AVG. BLOOD SERUM (MG. %)	BLOOD SERUM (MG. %) (EXTREMES)
<i>A. Noncardiac Group</i>				
Pneumonia	12	16	1.96	1.23-2.56
Cholelithiasis	9	17	2.02	1.38-2.60

Total groups A and B	197	312	2.19	1.23-3.54
<i>C. Chronic Nephritis</i>				
Chronic nephritis	4	13	3.31	1.59-4.60

CARDIAC GROUP

The cardiac group numbered 103, of whom 54 had hypertensive heart disease. The magnesium level in this condition is still a mooted question. Wacker and Fahrig¹³ state that magnesium is the only mineral found in increased concentration in the serum in essential hypertension. Their average magnesium value was 2.41 as compared with their normal of 2.28. In a group of 15 hypertensive patients without severe renal damage Walker and Walker¹⁰ found an average value of 2.36, as compared with their normal value of 2.2 in normal active young adults, and 2.3 in miscellaneous medical and surgical hospital cases. In 1923 Weil, Guillaumin, and Weismann-Netter²¹ found an increased serum magnesium in a few cases of essential hypertension, but to quote Walker and Walker:¹⁰ "These figures deviate so far, however, from the standards used by other authors that comparison is not possible." In our series were 23 ambulatory

hypertensive patients whose magnesium levels were 2.5 (1.67 to 3.31) and 31 ward hypertensive patients of whom many were decompensated with values of 2.27 (1.63 to 3.41). The grand average for the hypertensive group was 2.26, as compared with our normals of 2.12. The increase is very slight but is in conformity with the results obtained by the authors quoted above. Whether any significance is to be attached to so small a difference is certainly open to question.

The arteriosclerotic heart disease group numbered 35 patients in whom 66 magnesium determinations were effected. The average value was 2.23 mg. per cent, with extremes of 1.57 to 3.54. In the miscellaneous heart disease group were 14 patients in whom 17 blood magnesium studies were made. The group was heterogenous and included 4 cases of chronic rheumatic heart disease, 2 of congenital heart disease, one of acute rheumatic fever, 3 of subacute bacterial endocarditis, one of syphilitic heart disease, one of scarlatinal heart block,³¹ and 2 of thyrotoxic heart disease. The average magnesium value for the foregoing group was 2.24 (1.29 to 3.30). It is noteworthy that the magnesium value for nonhypertensive patients with cardiac disorders is elevated to practically the same degree as in patients in the hypertensive group, though again emphasis must be laid on the fact that the increase is very slight (Table I).

NEPHRITIC GROUP

The question of the magnesium content of the serum in renal insufficiency is still in a state of flux. One group affirms that there is no retention of magnesium in renal insufficiency. In this group are Denis and Hobson,²² who obtained figures of 2.2 to 2.9 in 19 patients, Denis,²³ working in experimental nephritis, and Fishberg.²⁴ In 1923 Salvesen and Linder²⁵ reported 15 patients in whom they sometimes found a reduction and sometimes an increase in magnesium (1.5 to 4.6). Somewhat similar results were obtained a year later by Rabinowitch²⁶ (1.6 to 3.1). That magnesium is retained in renal insufficiency has been asserted by another group of investigators. Included are Becher,⁵ Becher and Hamann,²⁷ who found values of 2.7 to 5.7 in 10 cases; Walker and Walker,¹⁰ who found abnormally high serum magnesium values in 5 hypertensive persons with renal damage (2.07 to 4.20); Cope,⁹ who in 1936 found the serum magnesium considerably elevated in 5 patients with renal damage increased after intensive alkali administration (4 patients with readings over 4.00 and one with a reading of 6.84); Hirschfelder,^{28, 29} who in 1934 reported serum magnesium figures often considerably raised in renal inadequacy; and Brookfield,⁸ who confirmed the increase of serum magnesium in renal dysfunction in a series of 21 cases (values did not exceed 3.93).

In the present investigation, 4 cases of nephritis were studied. The average reading was 3.31 (1.89 to 4.60).

CASE 1.—L. F., a female, aged 24 years, had had chronic nephritis of a mild character for several years but no renal insufficiency. Blood magnesium values taken several weeks apart were 1.89 and 2.55.

CASE 2.—R. C., a male, aged 63 years, had hypertension with definite chronic glomerulonephritis but only slight renal insufficiency. Blood magnesium determinations within a period of two weeks were 2.90, 2.86, and 2.06 keeping pace with the patient's clinical improvement.

CASE 3.—C. B., a female, aged 17 years, had advanced chronic glomerulonephritis. Blood magnesium was 4.36 on admission, 4.17 on the sixth day, 3.99 on the seventh, and 4.36 on the thirteenth. She received 1 ounce of magnesium sulfate by mouth on the sixth and seventh days, and 1.5 ounces on the ninth, tenth, eleventh, and thirteenth days, as well as an intramuscular injection of 2 c.c. of 50 per cent magnesium sulfate daily from the eighth to thirteenth day inclusive.

CASE 4.—M. J., a hypertensive negress, aged 38 years, had chronic glomerulonephritis with extreme degree of renal insufficiency. Initial blood magnesium on admission to the hospital (July 16, 1937) was 2.8. She received intramuscular injections of 2 c.c. of 50 per cent magnesium sulfate twice daily from August 3 to August 16 inclusive. Blood magnesium level on August 5 was 2.90, on August 12, 3.68, and on August 16, 4.60. The patient became comatose on August 19 and died the following day. Post-mortem examination confirmed the presence of an advanced glomerulonephritis. The results obtained bear out Brookfield's findings that an increase of serum magnesium is almost invariably present in renal dysfunction and corroborate his failure to disclose magnesium levels sufficient to produce coma as advanced by Hirschfelder.²⁹

URINARY MAGNESIUM

There are very few recorded experimental studies covering the level of the urinary magnesium. Cope⁹ recorded the basic urinary output of magnesium in one patient as 50 mg. per day. Walker and Walker¹⁰ found the twenty-four-hour urinary output in a group of normal active young adults to average 103 mg. (32.5 to 307.0 mg.) and 86 mg. (5 to 243 mg.) in a group of miscellaneous medical and surgical hospital patients. In 8 young adults Weber³⁰ recently reported the average daily urinary excretion of magnesium to be 83.9 to 132.1 mg. In our series the average daily excretion of 57 patients on admission to the hospital was found to be 105.5 mg., with values ranging from 17.3 to 285.0 mg. The values agree closely with those obtained by Walker and Walker. Such high variations as we obtained might readily be expected a priori when the great range of the individual diet is considered.

In several patients intramuscular injections of magnesium sulfate were given with a consequent reflection in the urinary output. In a hypertensive patient the initial urinary output was 45.3 mg. After 2 c.c. of 50 per cent magnesium sulfate were injected intramuscularly twice daily for four days, the urinary output rose to 102.9 and to 140.7 mg. the subsequent day.

In a patient with arteriosclerotic heart disease the initial urinary value was 80.0, rose to 158 the day following the intravenous injection of 15 c.c. of 10 per cent magnesium sulfate, reached 298.0 following the injection of 2 c.c. of 50 per cent magnesium sulfate intramuscularly twice daily for four days, and rose to a peak of 416.1 after the intramuscular injections were continued for eleven days more. No correlation could be established between the urine output and the blood level.

CONCLUSIONS

1. A total of 325 determinations of the blood serum magnesium were made in 201 medical cases with no disturbance of mineral metabolism.
2. A total of 312 determinations in 197 of the patients (excluding the 4 nephritic patients in the series) showed an average value of 2.19 mg. per cent (1.23 to 3.54).
 - (a) A total of 138 magnesium tests in 94 noncardiac patients showed an average value of 2.12 per cent (1.37 to 3.11).

(b) Ninety-one magnesium tests in 54 hypertensive persons gave an average value of 2.26 (1.63 to 3.41).

(c) Sixty-six magnesium determinations in 35 arteriosclerotic heart disease patients showed an average value of 2.23 (1.57 to 3.54).

(d) Seventeen magnesium tests in 14 patients with various other forms of heart disease showed an average magnesium value of 2.24 (1.29 to 3.30).

3. In 4 cases of chronic nephritis with varying degrees of renal insufficiency the blood serum magnesium level was elevated to almost double the normal value (3.31) (1.89 to 4.60).

4. The average twenty-four-hour urinary output of magnesium in 57 persons was 105.5 mg. (17.3 to 285.0).

INFLUENCE OF GLYCEROL ON GLYCEMIA IN NORMAL AND DIABETIC INDIVIDUALS*

MAX WISHNOFSKY, M.D., ARTHUR P. KANE, M.D., WILLIAM C. SPITZ, M.D.,
SAUL MICHALOVER, M.D., AND CHARLES S. BYRON, M.D.
BROOKLYN, N. Y.

THE relationship of substances other than hexoses, especially those having three carbon atoms, to carbohydrate metabolism has received considerable attention. Our knowledge of the metabolism of some of these substances is, however, in many respects fragmentary. In this paper we shall concern ourselves with the metabolism of glycerol. Although much work has been done on this subject, there are certain important phases which have received only scant attention. Experimental work tending to elucidate these problems will be reported.

REVIEW OF LITERATURE

The metabolism of glycerol may be considered from the following standpoint: (1) glycogenesis, (2) antiketogenesis and ketolysis, (3) influence of hypoglycemic shock, (4) influence on blood sugar.

1. *Glycogenesis.* Catron and Lewis¹ found that the amounts of glycogen formed in the liver after two- and three-hour periods of absorption of glycogen from the gastrointestinal tracts of white rats were equal to those observed after absorption of equivalent amounts of glucose over the same periods. Shapiro² has completely confirmed these observations. Chambers and Deuel³ observe that a practically complete conversion of glycerol into glucose was exhibited by two phlorhizinized dogs. Sansum and Woodratt⁴ found that d,l-glycerol aldehyde was quantitatively converted into glucose as determined by measuring glycosuria in deglycogenated phlorhizinized dogs. They argued that this precludes the possibility of glycerol having a greater utilization rate than glucose itself in diabetic persons.

*From the Medical Service of Dr. E. L. Shlevin and the Department of Basal Metabolism of the Jewish Hospital, Brooklyn.

Received for publication, November 9, 1939.

2. Antiketogenesis and ketolysis. Although the antiketogenic action of glycerol was first noted by Hirschfeld in 1895, it was most convincingly demonstrated by Satta's experiments.^{2*} Shapiro² found that equivalent amounts of glucose and glycerol had equal ketolytic properties.

3. Influence on hypoglycemic shock. Voegtlin and Dunn⁵ observed that the symptoms of insulin shock (coma and convulsions) were completely relieved by intravenous or intraperitoneal injections of glycerol. Noble and Macleod,⁶ on the contrary, found that glycerol did not affect the symptoms of insulin shock in the slightest degree.

4. Influence on respiratory quotient. The only work on this subject is by McCann and Hannon,⁷ who compared the respiratory quotients in three normal persons after the ingestion of glycerol and glucose. They found that whereas a marked rise in respiratory quotient was produced by glucose, no rise occurred with glycerol. It should be mentioned that glucose and glycerol are not strictly comparable, for the respiratory quotient of glucose is 1, whereas that of glycerol is approximately 0.86.

5. Influence on concentration of blood sugar. Voegtlin, Thompson, and Dunn⁸ found that glycerol given to fasted rabbits produced a hyperglycemia of considerable extent and duration. This increase was not due to an increase in concentration of the blood. Studies on the influence of glycerol on glycemia in man have been scant. Kneip⁹ observed that glycerol given in doses of 0.5 to 0.6 Gm. per kilogram of body weight did not influence the blood sugar of one diabetic and four normal children. Belrens¹⁰ also found that a dose of 30 Gm. of glycerol did not give rise to hyperglycemia in one diabetic and three normal children.

Fats, such as tristearin or triolein, when completely saponified yield approximately ten parts by weight of glycerol to ninety parts by weight of higher fatty acids. As previously mentioned, Sansum and Woodyatt contend that glycerol does not have a greater utilization rate than glucose itself in diabetic persons. It has been customary in estimating the glucose value of a diabetic diet to consider fat as yielding 10 per cent by weight of glucose, and to put that glucose in the same category as that derived from starch.

Investigations on the influence of glycerol on blood sugar have been fragmentary and inadequate. In this paper results of experiments will be reported on the influence of glycerol on blood sugar on a fairly large number of normal and diabetic individuals. The question of the utilization rate of glycerol in diabetic persons will to some extent, for reasons given below, be elucidated by the results obtained.

METHOD OF PROCEDURE

Experiments were performed on 13 normal and 10 diabetic persons. Eighty grams of glycerol,* in sufficient aqueous solution to constitute a total of 500 c.c., were given to each person in the morning after a fast of fourteen hours. Specimens of blood were taken from the normal individuals before, and forty-five minutes, two, and three hours after the ingestion of the glycerol. The sugar

*In the recovery of glucose from glycerol, two molecules of glycerol yield one molecule of glucose and four atoms of hydrogen.
 $2C_3H_8O_2 \rightarrow C_6H_{12}O_6 + 4H$, or 80 Gm. of glycerol yield 78.2 Gm. of glucose.

content of the blood was determined by the Folin-Wu method. In the diabetic patients the blood specimens were taken at the same time with one exception, namely, one hour instead of forty-five minutes after ingestion.

ANALYSIS AND DISCUSSION OF RESULTS

As mentioned in the review of the literature, there has been a paucity of study on the influence of glycerol on glycemia. Voegtlin, Thompson, and Dunn⁸ found that glycerol given to fasted rabbits produces a hyperglycemia of considerable extent and duration. Kneip⁹ and Belhrens,¹⁰ on the other hand, observed that glycerol had no influence on the blood sugar in several normal and diabetic children.

Table I shows the concentrations of the blood sugar in 13 normal individuals at the fasting level and after the ingestion of 80 Gm. of glycerol. A definite rise in the concentration of the blood sugar is noted in 8 of the 13 persons.

Table II shows the concentration of glucose in the blood of 10 diabetic persons at the fasting level and after the ingestion of 80 Gm. of glycerol. In 8 of the 10 cases a definite rise in the concentration of the blood sugar is observed. This rise may be collated with that of a comparable group of diabetic persons who received 75 Gm. of glucose (Table III). It will be noted that the rise in the concentration of the blood sugar when glucose is given is markedly greater than after glycerol.

The question arises: To what extent is this difference the result of a difference in the rates of absorption of the two substances from the human gastrointestinal tract? There has, unfortunately, been no experimental work on this subject. As already mentioned, Catron and Lewis¹ found that the amounts of glycogen formed in the liver after two- and three-hour periods of absorption of glycerol from the gastrointestinal tract of white rats were equal to those observed after the absorption of equivalent amounts of glucose over the same periods. This would indirectly indicate that no significant difference in the rates of absorption of glucose and glycerol from the gastrointestinal tract exists.

Another question is whether the rise in the concentration of blood sugar after glycerol is produced by an increase in the concentration of the blood. As previously noted, Voegtlin, Thompson, and Dunn⁸ did not observe any increase in the concentration of the blood in rabbits after the ingestion of glycerol.

The point to be considered now is the capacity of the diabetic person to utilize glycerol as compared with glucose. As noted above, Sansum and Woodyatt⁴ contend that glycerol does not have a greater utilization rate than glucose in diabetic persons.

The greatest glycemia, and consequently glycosuria, occurs in diabetic patients during the two- to three-hour period immediately following a meal. This degree of glycemia varies even when different hexoses are given. Thus galactose will give rise to a lower blood sugar curve than an equal amount of glucose. Consequently, the diabetic person can utilize galactose better than glucose. This is strikingly more so with glycerol. As already shown, the blood sugar curve when glycerol is ingested is markedly lower than when an equivalent amount of glucose is taken. It must be concluded then that the diabetic individual has a greater capacity to utilize glycerol than glucose.

It should be mentioned that this matter is of more 'scientific than practical importance, for the amount of glycerol derived by the saponification of fat is small. Furthermore, the glycerol is produced at a slow rate.

CONCLUSIONS

1. The ingestion of glycerol produces an increase in the concentration of blood sugar in a majority of normal and diabetic individuals.
2. Diabetic persons have a greater capacity to utilize glycerol than glucose.

GUANIDINE-LIKE SUBSTANCES IN BLOOD*

VII. GUANIDINE AND OTHER BLOOD CONSTITUENTS IN EXPERIMENTAL ANOXEMIA

JEROME E. ANDES, PH.D., M.D., EDWARD J. VAN LIERE, PH.D., M.D.,
ERLENE J. ANDES, B.S., M.S., AND PAUL VAUGHN, B.S.,
MORGANTOWN, W. VA.

IT HAS been pointed out in the previous paper of this series¹ that a tendency for hyperguanidinemia has been reported in a number of conditions exhibiting spasticity or convulsions. Although a part of these abnormal findings or possibly all in some diseases, may be ascribed to faulty analytical methods or faulty interpretation, there is still sufficient data to make additional study worth while in this direction.

As already pointed out¹ recent work seems to have entirely disproved the thesis of a hyperguanidinemia in parathyroid insufficiency.²⁻⁸ The high values observed by previous investigators seem to be entirely due to faulty methods of

*From the Departments of Pathology and Physiology, West Virginia University School of Medicine, Morgantown.

Received for publication, November 20, 1939.

possibly to blood concentration from dehydration. There is more evidence, however, that the convulsive states associated with the toxemias of pregnancy and related disorders may have a definite relationship to the concentration of guanidine in the blood. Malmejae and co-workers,⁹⁻¹¹ Minot and Cutler,¹² and Andes, Andes, and Myers¹³ have found a definite increase in the blood guanidine concentration in the toxemias of pregnancy, especially in true eclampsia. Traut and McFate¹⁴ observed hyperguanidinemia in a case of dysmenorrhea accompanied by convulsions. The entirely negative findings of de Wesselow and Griffith,¹⁵ Stander,¹⁶ and Krieger¹⁷ throw considerable doubt on the value of these findings. Andes and co-workers¹³ have pointed out that hyperguanidinemia in eclampsia is usually accompanied by some degree of renal insufficiency, and suggest this factor as the probable cause of most of the increase (renal insufficiency is usually, if not invariably, accompanied by an increase in the blood guanidine concentration¹⁸). They did note, however, a definite hyperguanidinemia in two cases of eclampsia with convulsions not accompanied by nitrogen retention, and furthermore, pointed out that patients in convulsions tended to show higher values. They also demonstrated a definite increase in the blood guanidine in *normal* women after delivery.

Ellis, Neal, and Frazier¹⁹ have reported an increased blood guanidine content in epileptic persons, the increase roughly paralleling the severity of the clinical symptoms. Although their work has not been confirmed, the changes observed are so marked as to apparently relate the blood guanidine change to the convulsant state. In addition, Dodd and Minot^{20, 21} and also Schumacher,²² have noted a hyperguanidinemia in the convulsive states of childhood. It is the opinion of some that dehydration is an important factor in producing the blood changes in this last set of conditions, but such has not been proved to be the entire cause.

In an attempt to elucidate the entire problem, Andes and Emerson¹ administered various convulsive drugs to rabbits and dogs, but obtained entirely negative results as far as blood guanidine was concerned. There still remained the possibility that anoxemia of the muscles and other tissues might be an important factor. Dordi's observation²³ of the presence of a hyperguanidinemia in pneumonia is some evidence as to the probability of this relationship being present (even though Dordi attributed the change to liver damage rather than to anoxemia). This work was carried out to determine whether any relationship existed between anoxemia *per se* and the guanidine content of the blood.

EXPERIMENTAL

Dogs were used as experimental animals. Only large, or moderately large, animals were selected to minimize as far as possible any error due to the slight degree of anemia resulting from the withdrawal of the relatively large blood samples (15 c.c.). The animals were fasted twenty-four hours before the experiment began and were not even allowed water during the course of the procedure.

Anoxemia was produced by the use of a tank in which the pressure and temperature could be held quite constant. The altitude in feet was computed by the barometric pressure inside the tank; likewise the partial pressure of oxygen. The period of anoxemia varied from thirty minutes to over seven and

one-half hours. The altitudes used varied from 18,000 to 24,000 feet (oxygen pressures of 80 to 53 mm. Hg, respectively). It is believed that this degree of anoxemia (especially in the seven-and-one-half-hour periods) is entirely ample to bring out any alterations in the blood chemistry that might be observed in life during anoxemia resulting from a spastic state.

In the first group of animals two dogs were used for each experiment: one as a control and one for the anoxemic experiment. Both dogs were anesthetized with sodium barbital and sacrificed after the experiment. The use of a separate control was decided upon to eliminate the possible error from blood loss due to the withdrawal of blood samples. The anesthetic served to obviate errors arising from muscular activity and dehydration during the period of anoxemia. In the second group of animals the same dog was used as a control, that is, samples were withdrawn before and after the period of anoxemia. No anesthetic was employed in this group and only relatively large animals were chosen.

Blood sugar, urea, and carbon dioxide capacity were determined by standard analytical procedures. Blood guanidine was estimated by the method of Andes and Myers.²⁴ Hemoglobin was measured by both photoelectric and colorimetric procedures. The determinations were all made immediately after the blood was withdrawn. The results are given in Table I. The table is divided into two parts in order to separate the two groups of animals.

DISCUSSION OF RESULTS

The findings are essentially negative in both groups of animals except for the blood urea, hemoglobin, and cell volume. The blood urea increase is significant although small. No explanation can be given for this change other than the effect of anoxemia on kidney function. The amount of hemoconcentration present, as denoted by the values for hemoglobin and cell volume, was too small to account for all this increase in the concentration of blood urea. The changes in the hemoglobin and cell volume were about what one would expect from the degree of anoxemia present. The values for guanidine and blood sugar were not significantly changed by the experiment. It will be noted that the glucose content of the blood is abnormally high in the group of animals in part A, Table I. This is presumably due to the fact that these animals received ether prior to the administration of barbital. The lack of further rise of blood sugar in the experimental animals may be due to the inhibiting effect of barbiturates on epinephrine release which would otherwise be produced by anoxia. The group of animals in part B, Table I received no anesthesia. Here again there is a lack of hyperglycemic response to anoxia. It must be pointed out, however, that the blood samples were drawn after four hours or more of anoxia.

The fall in the carbon dioxide capacity in the second set of animals is significant, but it is no more than one would expect from the amount of hyperpnea produced by the lack of oxygen and the additional hours of starvation. In the first group of animals the values for the carbon dioxide capacity are too erratic to be of any significance.

SUMMARY

1. Under the conditions described in this paper definite increases in the values of blood urea, hemoglobin, and volume of red blood cells were observed in anoxemic dogs. The guanidine content in the blood, however, was unchanged.

2. Some factor other than anoxemia must be sought as the cause of the hyperguanidinemia found in convulsive states.

A COMPARISON OF THE CHLORIDE CONCENTRATIONS IN WHOLE BLOOD AND SPINAL FLUID*

ROGER S. HUBBARD, PH.D., AND GILBERT M. BECK, M.D.
BUFFALO, N. Y.

IT IS generally believed that spinal fluid is formed from the fluids and solutes of the blood, and that the composition of the former medium reflects more or less closely that of the latter.¹ Comparative studies of these fluids have been extensively carried out in this country by Fremont-Smith and various co-workers.²⁻⁶ In part as a result of these and similar studies, the thesis has been developed that spinal fluid can be properly regarded as a modified dialysate of plasma. As this thesis has been adequately presented and discussed in various recent textbooks,⁷⁻⁹ a review of the history of the problem will not be given here.

The majority of the papers which have dealt with this subject have had for their purpose an examination of the evidence favoring or criticizing the thesis just stated. This has led previous investigators to carry out their determinations under certain specified conditions. Since the spinal fluid is apparently, at least in part, a dialysate of blood plasma,^{1, 10} precautions have been taken to secure specimens for analysis which shall resemble as closely as possible plasma as it exists in the body—the so-called “true plasma.” Blood has been collected without stasis under oil, and the cells removed from the specimen by centrifuging without contact with air. These precautions are taken to avoid changes in the carbon dioxide tension and the migration of chloride ions between the cells and plasma, that is, the so-called “chloride shift,” which results from changes in this tension.¹¹ Specimens of blood and fluid have regularly been drawn after a night's fast when the effects of the ingestion of food and water are at a minimum.

Since the determination of the chloride content of the spinal fluid has been found to be of value in the diagnosis of meningitis, particularly of tubercular meningitis,^{1, 14, 15} such analyses are frequently requested of clinical chemical laboratories. It seemed desirable to analyze blood and spinal fluid taken simultaneously in order to call the clinician's attention to the presence of a lowered chloride in the blood when such existed. This should decrease any tendency to attach too much specificity to the results of the spinal fluid analyses. It was hoped also that such a procedure would make it possible to detect the effect upon the spinal fluid chloride concentration of factors not associated with variations in the blood, such as changes in the protein concentration of the spinal fluid^{2, 4} and possibly of the replacement of chloride by lactic acid formed during the destruction of sugar by organisms and enzymes.²

Soon after this program was instituted it was found that these specimens of spinal fluid submitted for analysis frequently were taken from patients not in the postabsorptive state. It was also recognized that under the conditions existing in the clinic, the samples of blood obtained were as a rule not suitable

*From the Buffalo General Hospital and the Medical School of the University of Buffalo.
Received for publication, March 11, 1940.

for the preparation of "true plasma." The procedure was, therefore, definitely modified from that followed by Fremont-Smith and his co-workers. Specimens were drawn at any time during the day, and the whole blood was chosen as the material to be used for the control analyses. The method of Whitehorn¹⁸ was used for the determination of chlorides in both blood and fluid.

It was recognized that this procedure was not as well adapted to the study of the physiologic problem involved as was that employed by the investigator already cited. However, it was felt that one principal source of error, that due to variations in the concentration of red blood cells which are relatively low in spinal fluid chloride, could be controlled by routine blood counts. The other chief sources of error, variations in the chloride concentration in the red blood cells, and failure of the spinal fluid and blood to reach a condition of approximate equilibrium were necessarily ignored.

We were not able to find any data which might serve as a base line to determine the usual ratio between the whole blood and spinal fluid chloride concentrations. We have, therefore, undertaken to establish such a standard by a statistical analysis of our own material. Because we feel that other clinics are probably confronted by problems similar to our own, we are presenting the results for publication. In order to compare the relationship with that obtained under more nearly ideal conditions, we have analyzed the 331 determinations made upon true plasma and spinal fluid, obtained in the postabsorptive condition, published by Fremont-Smith and his co-workers.^{5,6} The character of the clinical material upon which these earlier studies were based seems to have been similar to that from the wards and out-patient department of the Buffalo General Hospital, but the number of normal cases was apparently somewhat greater in the series of the plasma determinations. To facilitate comparison of the two sets of data the results have been expressed according to standard statistical methods.

Table I shows the distribution of the separate values for whole blood and spinal fluid of the 225 analyses made at the Buffalo General Hospital. Inspection of the table shows that there was a marked correlation between the chloride content of the two fluids in the various specimens. The values of the ratio $\frac{\text{spinal fluid chloride}}{\text{whole blood chloride}}$ are given in the table. These were neither absolutely constant nor wholly independent of the blood and spinal fluid chlorides. They apparently tended to increase slightly as the concentration of chloride in the spinal fluid increased, and to decrease as the concentration in the blood increased. The data on the chloride content of the plasma and the spinal fluid presented in the papers of Fremont-Smith and his co-workers are given in Table IA. It is evident that the range of values is much less than that shown by our own results. The difference between the ranges of the whole blood and of the plasma figures is readily explained, for the composition of the plasma is much more nearly constant than is that of blood, as variations in the number of red blood cells, containing relatively small amounts of chloride, do not affect the latter figure. Two factors appear to have produced the difference between the distributions of the spinal fluid values in the two series. One of these probably was a difference in the method of selection of the cases studied; the other was

fact that Fremont-Smith's studies were made upon specimens obtained in the postabsorptive state when there is relatively little variation in the composition of all body fluids. In our own series the effect of the ingestion of water and of salt was unquestionably marked in some instances. Except for the difference in the "spread" of the figures, Table IA bears a close resemblance to Table I. The correlation between the plasma and spinal fluid chloride values is marked, and the values of the ratio $\frac{\text{spinal fluid chloride}}{\text{plasma chloride}}$ tend to vary directly as the spinal fluid values, and inversely as the plasma chloride concentrations.

The correlation coefficients based upon these analyses are given in Table II. In both series the correlation between the chloride of the spinal fluid and the chloride of the plasma and of the whole blood was positive and marked. The parallelism between the spinal fluid and plasma chlorides was closer than was

TABLE II
CORRELATION COEFFICIENTS

	BLOOD OR PLASMA NaCl AND SPINAL FLUID NaCl	BLOOD OR PLASMA NaCl AND RATIO	SPINAL FLUID NaCl AND RATIO
Fremont-Smith Plasma 331 determinations	$+0.811 \pm 0.013$	-0.467 ± 0.029	$+0.091 \pm 0.037$
Hubbard and Beck Whole blood 225 determinations	$+0.766 \pm 0.018$	-0.483 ± 0.051	$+0.118 \pm 0.044$

that between the spinal fluid and the whole blood chlorides, as would be expected from the probable mechanism involved for the spinal fluid is apparently formed directly from the plasma. The existence of a slight positive correlation between the values of the ratio $\frac{\text{spinal fluid chloride}}{\text{whole blood (or plasma) chloride}}$ and of spinal fluid chloride suggested in Tables I and IA is confirmed to some extent by the correlation coefficients. Analysis of both series of data gave slight positive coefficients, which were probably, but not certainly, significant. We believe that this parallelism results from the relationship between the amount of protein and of chloride in the spinal fluid discussed previously by Merritt and Fremont-Smith,⁹ and shown for our own data in Table III. If the protein concentration affects directly the spinal fluid chloride, and is itself independent of variations in the chloride of the blood and plasma, values of the ratio should parallel values of the spinal fluid chloride, i.e., variations in the spinal fluid chloride will to some extent, be independent of variations in the blood chloride concentration.

Table II also shows that a significant negative correlation existed between the values of the ratio and the chloride concentration of the whole blood or plasma. While a slight negative correlation might arise from the method by which the ratio is calculated (for increases in the denominator of a fraction must have some tendency to cause decreases of the value of the fraction), it seems to us that the correlation is too close to be explained wholly in this way. We believe that variations in the plasma and the whole blood chloride sometimes do not cause changes of the usual magnitude in the concentration of that substance in the spinal fluid. One factor, and obviously an important one, has been discussed by Fremont-Smith.⁵ He suggested that it takes a fairly long period of time to establish an equilibrium between the chlorides in the blood and the spinal fluid. This was in accord with previous work, for it had already been shown that an equilibrium between the glucose concentration in the two fluids is reached rather slowly.¹⁵ He pointed out that the most pronounced divergence in values of the ratio from those expected occurred in patients who were losing chloride and water by emesis or who were receiving either chloride or water therapy. In our own series the same type of patient showed similar unusual relationships. It was noted, too, that in many instances ratios which deviated markedly from the average of the series were obtained on individuals who were showing marked variations in the chloride content of the spinal fluid. Such an "abnormal" ratio was not infrequently preceded or followed by an entirely "normal" ratio within one or two days. This strongly suggests that some delay in attaining equilibrium

Spinal fluid NaCl	642.7 ± 7.4	649.1 ± 9.3	76.41 ± 4.80	11.89 ± 0.74
Spinal fluid protein	0.224 ± 0.021	0.105 ± 0.026	0.237 ± 0.015	104.29 ± 6.53
Ratio $\frac{\text{spinal fluid NaCl}}{\text{blood NaCl}}$	1.522 ± 0.012	1.498 ± 0.015	0.1372 ± 0.0086	9.01 ± 0.58

had affected the results. It is, of course, not possible to decide whether the occurrence of an unusual relationship between the chlorides in blood and spinal fluid always result from such a simple cause as this, or whether more specific factors must sometimes be considered in explaining the lack of constancy of the ratio $\frac{\text{spinal fluid chloride}}{\text{blood (or plasma) chloride}}$.¹⁰

It has been stated that there is evidence that the protein content of the spinal fluid has a direct effect upon the concentration of the chloride. Protein determinations were made by the method of Hubbard and Garbutt¹⁸ upon 58 of the 225 specimens of spinal fluid upon which this study is based. A statistical analysis of the results is shown in Table III. The correlation coefficients of the small series do not differ greatly from those of the larger one of which it forms a part. There was no relationship between the protein in the spinal fluid and the concentration of chloride in the blood. There were negative correlations between the spinal fluid protein on the one hand and the spinal fluid chloride and the values of the ratio $\frac{\text{spinal fluid chloride}}{\text{whole blood chloride}}$

on the other hand. Such a relationship would be expected if the spinal fluid protein causes, or is fairly regularly accompanied by, decreases in the spinal fluid chloride. Such decreases may result from a diminution of the usual difference between the protein concentrations of plasma and spinal fluid.'

The usual statistical constants for the figures obtained in our own series, for those calculated from the data of Fremont-Smith, and for the 58 cases upon which protein analyses were available are given in Table IV. There is need of only brief comment upon this table. The blood and spinal fluid chloride values showed a high degree of variability and gave distribution curves which departed markedly from the symmetrical form, as shown by the large difference between the mean and median values. The ratios calculated from these observed data showed relatively little variability, and, while not perfectly symmetrical, were nearly so. As expected, the values of ratios calculated from the data of Fremont-Smith, based upon analyses of true plasma, appeared to be more nearly constant and to show more symmetrical distribution than did those of ours based upon

Chart 1.

determinations of the whole blood chloride. The difference between the two sets of values was not as great, however, as we had expected it would be.

Since it is hoped that the results of this study will be of value to other clinics in which spinal fluid analyses are carried out, Chart 1 has been prepared to show the distribution of the values of the ratios $\frac{\text{spinal fluid chloride}}{\text{whole blood chloride}}$ and $\frac{\text{spinal fluid chloride}}{\text{plasma chloride}}$. The chart shows graphically the distribution indicated in statistical terms in Table IV. These ratios show such constancy that either may be useful in checking the probable significance of spinal fluid analyses. The results based upon studies of true plasma were obviously somewhat more satisfactory than were those based upon analyses of whole blood.

CONCLUSIONS

Statistical analysis of a series of simultaneous determinations of whole blood chloride and spinal fluid chloride shows that a high degree of correlation exists

between the two sets of values. While the agreement of the spinal fluid chloride with the whole blood chloride was not as close as was the agreement of the former with plasma concentration, the agreement was nevertheless close enough to show that simultaneous determinations of the chloride content of whole blood can serve as a useful check upon the significance of spinal fluid analyses. Such controls should be especially valuable in clinics where the more complicated procedures cannot be readily carried out. It could be shown that three factors influence the value of the ratio between spinal fluid and whole blood chloride: (1) the protein content of the spinal fluid; (2) the concentration of cells in the blood; (3) the failure of the blood and spinal fluid to reach equilibrium when the fluid and salt content of the body were rapidly changing. Whether any other factor or factors influence the equilibrium, and so specifically affect the concentration of chloride in the spinal fluid, could not be determined.

LABORATORY METHODS

GENERAL

A STANDARDIZED TECHNIQUE FOR SEDIMENTATION RATE*

J. W. CUTLER, M.D., PHILADELPHIA, PA.

LACK of a universally accepted technique for recording erythrocyte sedimentation rate has been a serious block to a more widespread adoption of this simple test in general practice. The great majority of techniques described have complicated the problem, making comparison of results by the various procedures difficult.

All techniques described were originally developed empirically. In each the unit of comparison (usually the total drop at the end of one hour expressed in millimeters), while it reflects the rapidity of sedimentation in a general way, fails to give an accurate idea of the rate of settling. Furthermore, an arbitrary determination at the end of a stated interval, such as one hour, also reflects anemia because of the packing of the cells in the bottom of the tube within the first hour in rapidly settling blood. Efforts to "correct" for anemia, as advocated by some investigators, have failed to yield consistent sedimentation findings.

The object of the present paper is to describe a technique that is based on principles applicable to all tubes. The method is simple, and requires no correction for anemia. In a way this technique is a modification of the previous Cutler method, but the approach and interpretation are totally different. To understand it, it is necessary to keep in mind the present concept of the factors believed responsible for the rapid settling of the erythrocytes.

It is generally accepted that rapid sedimentation is dependent upon the formation of large aggregates or rouleaux of red blood cells and that rouleaux once formed settle at a given rate of speed, more or less in accordance with Stokes' law of hydrodynamics—the larger the aggregate the more rapid the settling and vice versa (Figs. 1 and 2). It has been established that the arrangement of the red blood cells in rouleaux and the size of the rouleaux are effects brought about almost entirely by the plasma and are specific for that plasma, and that the size and number of cells in suspension, as in anemia, have little influence on this specificity of the plasma.¹ The exact nature of the changes in the plasma which bring about the formation of large rouleaux is not known, but it is generally believed that the hydrophilic substances present in the plasma, i.e., the proteins which vary in type and electrolyte combination, play

*From the Henry Phipps Institute and Graduate Hospital of the University of Pennsylvania, Philadelphia.

Presented before the Pathological Society of Philadelphia, January 11, 1940.

a predominant role, probably through surface dehydration or change in the water balance on the surface of the red blood cells.

Fig. 1.—Rouleaux formation in slowly settling blood. The rouleaux are small and consist of relatively few cells.

Fig. 2.—Rouleaux formation in rapidly settling blood. The rouleaux are large and consist of many cells. It is the increased mass of the large rouleaux that brings about rapid sedimentation. This fundamental fact underlies the technique for determining sedimentation rate described in the text.

THREE PHASES OF ERYTHROCYTE SEDIMENTATION

We are now in a position to study in detail the sedimentation phenomenon as recorded in the form of graphs. Four distinct types of graphs, a horizontal

line, a diagonal line, a diagonal curve, and a vertical curve (Fig. 3), have been recognized.² The horizontal line is normal and denotes slow sedimentation. The other graphs are abnormal findings and indicate various degrees of increased sedimentation. The vertical curve (Fig. 3D), which indicates the most rapid form of sedimentation, consists of three phases. The first is a slow phase, during which the cells are grouping themselves and forming aggregates. This aggregation period usually varies from five to fifteen minutes; occasionally it is as long as thirty minutes. Once formed, the aggregates fall uniformly, more or less in accordance with Stokes' law—the larger the aggregate the more rapid the fall. This is the second or settling phase and gives rise to the sedimentation phenomenon.

Fig. 3.—Typical graphs depicting erythrocyte sedimentation. A, horizontal line; B, diagonal line; C, diagonal curve; D, vertical curve. Only the horizontal line is normal. When the retarding influence of packing is absent, the rate of settling of the rouleaux once formed, is fairly uniform; this is best illustrated in graph B, where the rate is 2 mm. every five minutes.

The heavy part of each graph denotes the maximum settling in any five minutes during the hour and is a better guide to sedimentation rate than the sedimentation index (total drop at the end of one hour). Thus, graphs C and D have practically the same index (32 and 24 mm., respectively) but strikingly different maximum rates in five minutes (7 and 17 mm., respectively). Graph C is from a patient in her ninth month of pregnancy; graph D is from a patient with fatal carcinoma of the lung. Note that the maximum sedimentation rate in five minutes almost invariably occurs during the first thirty minutes and that no readings need be taken with the new technique beyond that time.

The aggregates settle at their respective speeds indefinitely, depending on the length of the tube, until they reach bottom. The aggregates that follow pack on top, and the packing stage, or third phase, of sedimentation sets in. Sedimentation during the packing stage is always slow. When all aggregates have settled tightly, sedimentation comes to a standstill.

It is apparent that by the time packing ensues, the sedimentation phenomenon has already taken place and that the packing of the cells represents only a rough hematocrit finding, recording the space in the tube occupied by the cells. The packing stage is the only phase of sedimentation that is ma-

terially influenced by the degree of anemia. The fewer the cells, the less volume they occupy.

The three phases, aggregation, sedimentation, and packing, are found in all graphs, in the horizontal normal as well as in the definitely abnormal vertical curve. The difference is in the time required to complete the second stage, or stage of sedimentation which depends upon the mass of the aggregates formed during the first or aggregation phase, which in turn is a function of the plasma. To study the sedimentation phenomenon, one should be concerned principally with the second phase, or phase of settling.

Fig. 4.—The influence of packing of the cells in the bottom of the tube (packing) on the rapidity of sedimentation in tubes 50, 100, 200, and 600 mm. long, respectively, and 5 mm. internal diameter. Readings every five minutes during the first hour (same sample of blood). In the first ten or fifteen minutes settling is slow in all tubes, for it is during this period that the red blood cells group themselves into rouleaux. Once rouleaux are formed, however, settling becomes rapid. Sedimentation reaches maximum 12 mm. in five minutes in the 50 mm. tube between fifteen and twenty minutes; 17 mm. in five minutes in the 100 mm. tube between twenty and twenty-five minutes; 45 mm. in five minutes between twenty and twenty-five minutes in the 200 mm. tube; and 50 mm. in five minutes between twenty-five and thirty minutes in the 600 mm. tube. From that point on (Indicated by arrows) sedimentation in five-minute periods becomes progressively slower in each tube because of the retarding influence of packing. Obviously the packing factor cannot be eliminated in tubes even 600 mm. long and no advantage whatever is gained in employing tubes longer than 50 mm. On the contrary, there are many disadvantages.

SEDIMENTATION RATE OF ROULEAUX

The object in the present technique was to determine the rate of sedimentation of the rouleaux during the phase of settling at a time when the rouleaux are formed and settling at a uniform rate of speed, uninfluenced by the period of aggregation of the red blood cells into rouleaux on the one hand, or their packing in the bottom of the tube on the other. Unfortunately, it is impossible

Fig. 5.—The length of tube is a decided factor in determining sedimentation rate, and this fact indicates the need for the adoption of a standard technique. The maximum drop in any five minutes in the 50 mm. tube is 1 mm.; in the 600 mm. tube, it is 2.5 mm. (same blood sample). The maximum rate in five minutes is reached much later in the 600 mm. tube than in the shorter 50 mm. tube.

Fig. 6.—Bizarre sedimentation rate findings. Once rouleaux have formed, the rate of fall is fairly uniform. However, at times bizarre findings are observed, the explanation for which is not entirely clear, but they are in all probability mechanical in nature. It is worthy of note, however, that these bizarre records are self-correcting. Thus, if sedimentation is unduly slow in five minutes, the next reading will be unduly rapid (curve B), and vice versa (curve C). This again illustrates the unreliability of a single reading in determining sedimentation rate. The bizarre findings, while not common, were observed more frequently in tubes 100 and 200 mm. long than in 50 mm. tubes, and more commonly during the second half hour.

to eliminate the retarding influence of packing on sedimentation in rapidly settling blood in any tube of reasonable length, whether it be 50, 100, 200, or 600 mm. long (Fig. 4). In rapidly settling blood, the slowing effect of packing on sedimentation becomes evident well within the first hour, and the sedimentation rate is less in every one of the tubes mentioned than it would be normally in tubes of indefinite length. The only difference observed in tubes of 600 mm. or less in length was in the degree of slowing. It was also discovered that even in slowly settling blood, the rate of settling of the rouleaux, although slow in all tubes, is faster the longer the tube, and that the length of the tube is an important factor in determining sedimentation rate (Fig. 5). For practical reasons, therefore, it is necessary to determine the *maximum* sedimentation rate that the rouleaux can attain in a unit of time, e.g., five minutes, in a tube of fixed length. Such a unit would express the sedimentation velocity of the rouleaux at a time when it was *least* influenced by packing of the cells, and may be referred to as the maximum sedimentation rate or M.S.R., or simply sedimentation rate. Such a determination, for reasons mentioned above, would be independent of the anemia factor when present, and would be a true expression of sedimentation rate in that it denotes distance per unit of time and not distance at the end of a specified time as at present.

In the Cutler tube the maximum sedimentation rate in any five minutes can be determined during the first thirty minutes of settling, and no readings need be taken beyond that time, as the following study shows:

TABLE I

ANALYSIS OF 18 CASES (12.5% OUT OF A CONSECUTIVE SERIES OF 144) WITH SEDIMENTATION RATE FASTER IN A 5-MINUTE INTERVAL DURING THE SECOND 30 MINUTES OF SETTLING (CUTLER TUBE)

NO. OF CASES	M. S. R. IN ANY 5-MIN. PERIOD DURING FIRST 30 MIN. (MM.)	M. S. R. IN ANY 5-MIN. PERIOD DURING SECOND 30 MIN. (MM.)	DIFFERENCE (MM.)
3	0.5	1.0	0.5
2	1.0	1.5	0.5
1	2.0	2.5	0.5

1	2.0	4.5	2.5
1	4.0	7.0	3.0
1	2.5	6.0	3.5
18			

Only in the last three cases (2 per cent in this series) is the difference of some clinical significance.

Samples of blood from 144 consecutive patients were studied for their sedimentation rates by distributing parts of each sample into tubes 50, 100, and 200 mm. in length, respectively, and 5 mm. internal diameter. Readings were made every five minutes for one hour, and the results were recorded on sedimentation charts. (In an additional 93 cases simultaneous studies were made in 50 and 600 mm. tubes, respectively, but to simplify the presentation these are not discussed in detail.) The maximum settling in any five-minute period during the hour, after correcting for such bizarre findings as depicted in Fig. 6, was

determined for each sample of blood in each of the tubes studied. The results are recorded in Fig. 7. It will be noted that the M. S. R. made its appearance during the first thirty minutes of settling in the 50 mm. tube in 126 cases (87.5 per cent), in the 100 mm. tube in 126 cases (72.0 per cent), and in the 200 mm. tube in 81 cases (56.0 per cent). In the 600 mm. tube in many instances the M. S. R. did not make its appearance until the second hour of settling (Fig. 5).

Since a variation in the M. S. R. of 0.5 to 1 mm. is within normal limits,³ a critical analysis of the 18 cases (12.5 per cent) in the Cutler series (50 mm. tube) with a maximum sedimentation rate in five minutes greater during the second thirty minutes of settling (Table I), discloses that in only three cases, the last three in the table, was the difference of some clinical significance, but not sufficiently great to discredit the findings in the first thirty minutes. Thus there is in this series a potential error, of little importance clinically, of approximately 2 per cent (3 cases in a consecutive series of 144) by limiting all readings to the first half hour when determining the M. S. R. This is a much lower percentage of error than with tubes of greater length, and is a distinct advantage in using the Cutler tube.

Fig. 7.—The maximum sedimentation rate (M.S.R.), expressed as the maximum settling in millimeters in any five minutes, was determined independently for each blood sample, in 50, 100, and 200 mm. tubes, respectively, and the frequency with which the M.S.R. occurred at different time intervals is recorded. In the 50 mm. tube the M.S.R. made its appearance in the first thirty minutes in 87.5 per cent of the blood samples studied (126 cases out of a consecutive 144). On the other hand, when the same bloods were studied in 100 mm. and 200 mm. tubes, the M.S.R. occurred in the first thirty minutes in only 72 and 56 per cent of cases, respectively. For details see text.

Other studies already completed³ are additional proof that the Cutler tube of 50 mm. length and 5 mm. internal diameter will give sedimentation rate information with less chance of error and with greater convenience and efficiency, because such technical factors as position of tube, have less effect than in longer tubes. It would seem justifiable, therefore, to agree on a tube of this length in an effort to standardize the technique.

DETAILS OF TECHNIQUE

The essential features of the new technique are as follows:

Cutler sedimentation tubes of 1 c.c. capacity are used, graduated into 50 mm. divisions, with 0 at the 1 c.c. level. One-tenth of 1 c.c. of 3.8 per cent sodium citrate solution (age does not matter) is aspirated into a 2 c.c. syringe and blood, obtained by puncture of a suitable vein, drawn to the 1 c.c. mark (for convenience, larger quantities of blood and citrate, but in the same proportion, may be used). After drawing back the barrel of the syringe about 1 cm., the blood and citrate are gently mixed by tilting the syringe backward and forward several times. The contents are then emptied into the sedimentation tube up to the zero mark, and the tube is placed in a special rack. The position of the sedimenting column of erythrocytes is determined every five minutes for one-half hour. The observations are recorded on charts that have been designed for the purpose on which the horizontal lines represent the divisions on the tube and the vertical lines the intervals of time. Graphs are then constructed, which not only show the position of the sedimenting column of erythrocytes at any period of time during the first half hour, but also portray changes in velocity that occur during the process of sedimentation. This leaves a permanent, visual record, easily comprehended and readily compared. The biggest drop in any five-minute period during the first half hour is the maximum sedimentation rate in five minutes (M.S.R.) that the rouleaux will attain in the Cutler tube, and becomes the unit of comparison.*

EVALUATION OF SEDIMENTATION RATE

The evaluation of sedimentation rate presented in this paper, expressed as the maximum settling of the rouleaux in five minutes during the first thirty minutes (Cutler tube), is based on an analysis of 1,068 consecutive cases. In each instance sedimentation readings were made every five minutes for one hour, and graphs were constructed. At the same time the maximum sedimentation rate in any five-minute period during the first thirty minutes of settling (M.S.R.) was determined for each graph. The graph and maximum sedimentation rate were then compared and a tabulation was made (Table II). Cases with a maximum sedimentation rate of 2 mm. or less were restudied as a separate group, and a detailed comparison was made between the maximum sedimentation rate and the sedimentation index (Table III).

It has been generally accepted that in the original Cutler technique a graph represented by a horizontal line is a normal sedimentation finding and that all

*In large institutions where it is desirable to include the sedimentation rate in the routine blood determinations and heavy laboratory schedules make immediate examination impractical, reliable and accurate results will be obtained by distributing tubes containing 0.2 c.c. of 3.8 per cent sodium citrate solution and having 2 c.c. of blood syringed into this container at the time blood is drawn for other determinations. This amount suffices for use in the 1 c.c. Cutler tube (50 mm. by 5 mm. column). The test may be performed at any time within four hours of citration. The time interval clock for announcing five-minute intervals will be found time-saving and practical.

other graphs are pathologic findings of increasing clinical significance. Thus a diagonal line with a sedimentation index of 15 mm. or less, although pathologic, is usually associated with disease of slight intensity, as a rule without clinical manifestations of toxemia; a diagonal line with an index of 16 mm. or more with disease of slight to moderate intensity, but accompanied as a rule by constitutional symptoms of slight degree; a diagonal curve, with disease of moderate intensity accompanied usually by toxemia of moderate degree; and a vertical curve, with disease of marked intensity, associated almost invariably with marked constitutional symptoms. In the same technique the sedimentation index represents the total sedimentation at the end of one hour expressed in millimeters. A sedimentation index of 8 mm. or less is considered normal; an index of 9 mm. or more, pathologic.

With these explanatory remarks the following interpretation may be placed upon the maximum sedimentation rate in five minutes (M.S.R.).

TABLE II

EVALUATION OF MAXIMUM SEDIMENTATION RATE IN TERMS OF SEDIMENTATION GRAPH
(BASED ON 1,068 CONSECUTIVE CASES)

There is a distinct correlation between maximum sedimentation in five minutes and sedimentation graph. H.L., horizontal line; D.L.—15, diagonal line, sedimentation index 15 mm. or less; D.L.—16, diagonal line, sedimentation index 16 mm. or more; D.C., diagonal curve; V.C., vertical curve; M. S. R. is expressed in millimeters.

Normal Sedimentation Rate.—In Table III are analyzed 610 cases in this study with a maximum sedimentation rate of 2 mm. or less. These are subdivided into five groups: (1) those with an M.S.R. of 0.5 mm. or less; (2) an M.S.R. of 1 mm., but with the 1 mm. rate not repeated more than twice during the first thirty minutes of settling, expressed in the tables as M.S.R.¹⁻²; (3) an M.S.R. of 1 mm., but with the 1 mm. rate repeated three or more times during the first

thirty minutes of settling, expressed in the tables as M.S.R.³⁻⁵; (4) an M.S.R. of 1.5 mm.; and (5) an M.S.R. of 2 mm. Each maximum sedimentation rate is compared with the corresponding sedimentation index as defined above, and a table of parallel values is constructed.

It is apparent from a study of Table III that only a maximum settling in five minutes of 1 mm. or less, with the maximum rate of 1 mm. in five minutes not repeated more than twice during the first thirty minutes of settling, is normal, and that only such values correspond to a sedimentation index of 8 mm. or less in the original Cutler technique. When the maximum sedimentation rate in five minutes is 1 mm., but the rate is repeated three or more times during the first thirty minutes, the rate, as judged by the sedimentation index, is increased and therefore pathologic.*

TABLE III

EVALUATION OF MAXIMUM SEDIMENTATION RATE IN TERMS OF SEDIMENTATION INDEX

Only a maximum sedimentation rate in five minutes (M. S. R.) of 1 mm. or less with the 1 mm. rate not repeated more than twice during the half hour is normal. It would not be grossly incorrect, however, in order to simplify matters, to speak of a maximum settling in five minutes of 1 mm. or less as normal, and anything more as abnormal.

MAXIMUM SEDIMENTATION RATE

18					1	10
19					1	8
20					1	5

Increased Sedimentation Rate.—Table II compares the sedimentation graph with the corresponding maximum sedimentation rate, and permits the following evaluation of an increased maximum sedimentation rate:

(1) A maximum sedimentation rate of 1 mm. (repeated three or more times), but not greater than 2 mm., corresponds to a diagonal line with a sedimentation index of 15 mm. or less, and represents disease of slight intensity, usually without constitutional symptoms. (2) M.S.R. of 2.5 to 4 mm. corresponds to a diagonal line with an index of 16 or more and represents disease of slight to moderate intensity, usually associated with some clinical manifestations of toxemia. (3) A M.S.R. of 5 to 9 mm. corresponds to a diagonal curve

*The number of times the maximum rate in five minutes repeats during the first thirty minutes of settling gives additional and detailed information on the rapidity of sedimentation—the more times it repeats the more rapid the settling. To simplify matters, although not strictly correct, one can consider a maximum settling in five minutes of 1 mm. or less as normal, and anything more as abnormal.

and represents disease of moderate intensity, usually associated with moderate constitutional symptoms. (4) A M.S.R. of 10 mm. or more corresponds to a vertical curve and represents disease of marked intensity characterized, as a rule, by marked constitutional symptoms.

This indicates the requirements for precise determination and interpretation of the sedimentation rate. The unit maximum sedimentation rate in five minutes (M.S.R.) needs no correction for anemia; it cannot be misunderstood for it is determined objectively. It is important to remember that the sedimentation rate of the rouleaux is different in tubes of different length. Should one desire to use a tube longer than 50 mm. the same principles hold true, but a different scale must be set up. The different scales, however, have a definite relationship to each other and can be readily compared. Thus, compared with the 50 mm. tube, the rate is one-third faster in the 100 mm. tube, twice as fast in the 200 mm. tube, and three to four times faster in the 600 mm. tube, a ratio of approximately one-third increase in sedimentation for every 50 mm. increase in the length of the tube.

SUMMARY

A new technique, a modification of the Cutler, is presented for determining erythrocyte sedimentation rate; it is based on the fundamental fact that it is the size of the rouleaux that determines the rate of settling. This technique is precise, simple, and time-saving. The results are easy to interpret and need no correction for anemia. The method embodies principles that are applicable to all tubes. The essential features are as follows:

Cutler sedimentation tubes of 1 c.c. capacity are used, graduated into 1 mm. divisions, with 0 at the 1 c.c. level. One-tenth cubic centimeter of 3.8 per cent sodium citrate solution and 0.9 c.c. of blood obtained by puncture of a suitable vein are gently mixed in a 2 c.c. syringe and poured into the sedimentation tube, and the tube is placed in a special rack. The position of the sedimenting column of erythrocytes is determined every five minutes for one-half hour and is recorded on special charts. The maximum settling in any five minutes during the half hour is the sedimentation rate and becomes the unit of comparison.

For all practical purposes a maximum settling in five minutes of 1 mm. or less is normal. Everything else is abnormal and therefore pathologic. Generally speaking, maximum rates in five minutes between 1.5 and 4 mm. indicate disease of slight intensity; rates of 5 to 9 mm. indicate moderate intensity, and rates of 10 mm. or more, marked intensity.

Evidence is presented that the 1 c.c. Cutler tube is a practical tube for sedimentation rate determination, giving reliable and accurate results under average conditions. This tube appears suitable for standardization of technique.

The sedimentation charts may be obtained from Hartenstine Printing House, 206 DeKalb Street, Norristown, Pa.; the tubes, from Arthur H. Thomas Co., 230 S. 7th Street, Philadelphia, Pa.

RAPID DIAGNOSTIC METHOD FOR TESTING THE VIRULENCE OF CORYNEBACTERIA*

VERA B. DOLGOPOL, M.D., AND HELEN Y. MARKUS, M.T.
NEW YORK, N. Y.

VIRULENCE tests for the bacilli of the *Corynebacterium* group, carried out with pure cultures, require at least five to six days. While working with cultures of the *Corynebacteria* free from contaminating flora at the Laboratories of the Willard Parker Hospital, we succeeded in reducing to four days the time required for a report on the presence of toxin-producing diphtheria bacilli in swabs from the nose and throat. This was accomplished by culturing the material submitted for examination on a tellurite blood agar medium, and by using suspensions from pooled pickings of the *Corynebacteria* for virulence tests without subculturing them on other media.

Potassium tellurite, when incorporated in culture media in appropriate amounts, inhibits the growth of most pyogenic bacteria, without interfering with the growth of the bacilli of the *Corynebacterium* group (potassium tellurite media of Clauberg,¹ Pergola,² Anderson and co-workers,³ and Horgan and Marshall⁴). The colonies of the *Corynebacteria*, grown on these media from a material rich in pyogenic flora, reach in eighteen hours a greater size than on other media where they grow among numerous colonies of contaminants. Suspensions made from several colonies picked from tellurite media are heavy enough to be used for virulence tests. The few contaminants that have overcome the inhibitory action of the potassium tellurite, usually the staphylococci, are readily identified by the appearance of their colonies and, in doubtful cases, by means of smears.

METHOD

Culture Medium.—The medium used was a slightly modified one of Horgan and Marshall. The tellurite solution was prepared by autoclaving 1 Gm. of potassium tellurite in 100 c.c. of distilled water. Eight cubic centimeters of this solution mixed with 5 c.c. of defibrinated horse blood was kept in the icebox for from one to three days and then added to 100 c.c. of melted 2 per cent agar beef heart medium pH 7.4 to 7.6, at 50° to 60° C. The medium was distributed in Petri dishes. The plates remain good for about three weeks if kept in the icebox.

As the solubility of the potassium tellurite varies from one batch to another, and some of it may remain undissolved after autoclaving, the presumably 1 per cent solution from a new supply of the chemical was tested with a known culture of the diphtheria bacillus. If, after the use of 8 c.c. of the solution in

*From the Pathologic Laboratories of the Willard Parker Hospital, New York.
Received for publication, December 21, 1939.

the medium, the colonies of the diphtheria bacillus were small in eighteen hours, 7.5 c.c. was used instead, and the growth then was found to be satisfactory.

Preparation of the Suspension.—Swabs from the nose and throat were streaked on plates of the tellurite medium. The next morning the cultures were examined with a hand lens. Smears were made from portions of several colonies of various morphology, and stained with the Ponder stain in order to avoid inclusion of the staphylococci in the suspension. No attempt was made to identify the three types of the diphtheria bacillus or to exclude the diphtheroids. However, colonies of various morphology were included in the suspension. Five or more colonies of the *Corynebacteria*, picked off the plate, were suspended in 2 or 3 c.c. of broth which assumed a light gray color. When tested in Hopkins' tubes, the suspensions proved to contain 0.15 per cent of bacillary bodies.

Virulence Test.—Two-tenths cubic centimeter of the suspension was inoculated intracutaneously in the shaved abdomen of a guinea pig; three to four tests were made on one animal. A similar amount was injected intraperitoneally into another guinea pig which was used for the same number of control tests, and 500 units of diphtheria antitoxin was given subcutaneously. The guinea pigs were examined in 24, 48, and 72 hours. A black or purple area on the site of inoculation in the unprotected animal indicated the presence of a toxin-producing bacillus in the suspension. No discoloration and no inflammation of the skin was ever observed in the control animals.

In order to establish whether the results of the rapid virulence test were comparable with those obtained by the usual methods, 55 duplicate tests were made with suspensions of the *Corynebacterium* colonies grown on tellurite medium and with cultures of those bacteria isolated from ordinary blood agar plates.

Duplicate swabs were obtained from the material to be examined. One swab was streaked on the tellurite medium, and the suspension from the colonies of the *Corynebacteria* for the virulence test was made the next day, as described in the method; the final report on the virulence was ready on the fourth day. A duplicate swab was streaked on a plate of ordinary 5 per cent blood agar. In eighteen hours the colonies of the *Corynebacteria*, growing among the contaminants, were small, and those not contiguous with the colonies of the contaminants could not supply enough material for a bacterial suspension sufficiently heavy for the virulence test. Subcultures on Loeffler slants had to be made from these colonies, and from twenty-four to forty-eight hours more elapsed before a sufficient growth was secured for the bacterial suspension. The guinea pig was thus inoculated two or three days after the material had been received for the examination, and the virulence test was completed on the fifth or sixth day, or one or two days later than from tellurite plates.

In 54 cases the results of the virulence tests with the two bacterial suspensions were identical (28 cultures of toxic diphtheria bacilli, 26 cultures of non-toxic bacilli). In one case in which only 3 colonies of the *Corynebacteria* were available after eighteen hours' incubation on the tellurite medium, the suspension showed no toxin production, while the subculture from the blood plate revealed

the presence of toxin-producing bacilli. No discrepancy was observed when five or more colonies were used for the preparation of the suspension. Apparently, if the diphtheria bacilli are at all present in the material inoculated, at least one colony of toxin-producing bacilli is likely to be included in a suspension from five colonies.

The importance of pooling picked colonies for a single virulence test in order to avoid false negative results is mentioned by Fraser and MacNab.⁵

The incorporation of the potassium tellurite in the culture media does not affect the production of the toxin by the diphtheria bacilli, according to Clauser,⁶ Zopoth,⁷ and others.

No black discoloration of the guinea pig skin by the gray suspension of the tellurite-grown bacteria was ever observed in the antitoxin-protected animals. No discoloration other than toxic could, therefore, be expected in the nonprotected animals, and no false positive reactions were observed. However, we found it desirable to establish what amounts of the potassium tellurite might cause inflammation, necrosis, or discoloration of the skin. The use of 0.05 and 0.025 c.c. of a 1 per cent solution of potassium tellurite produced blackening of the site of intracutaneous injection; 0.015 c.c. produced a minute black dot, but smaller amounts left the skin unchanged. The amount of potassium tellurite in 0.2 c.c. of the bacterial suspensions used in the tests would be infinitely smaller than in 0.015 c.c. of a 1 per cent solution, so that no confusing discoloration of the guinea pig skin could be expected.

Suspensions of *Corynebacteria* grown on tellurite media were used occasionally for diagnostic virulence tests by other workers. Fraser and MacNab, in a review of the subject of virulence tests, mention in a brief paragraph the possibility of using these suspensions and indicate the need for pooling the suspensions from several colonies. Pavan,⁸ in a clinical article on the importance of virulence tests in patients and carriers of "modified diphtheria bacilli" indicates that crude (i.e., whole) cultures from slants of Pergola's medium have been used for bacterial suspensions.

While the use of *Corynebacteria* grown on tellurite media for the virulence tests is not new, its application to a four-day diagnostic test seems to be worth mentioning.

Four-day diagnostic virulence tests have heretofore been performed with suspensions from the original Loeffler slant growths ("field cultures"), as recommended by Havens and Powell.⁹ However, the presence of pyogenic contaminants in the washings from the crude cultures often produces a marked inflammation and suppuration at the site of intracutaneous inoculation, making the reading difficult.

Modified field cultures on Loeffler slants, with a diminished number of pyogenic contaminants, may be obtained by using subcultures from the rapid culture swabs of Brahdry, Lenarsky, Smith, and Gaffney.¹⁰ Their use also permits a four-day report on the virulence. However, this method requires subculturing after four hours. While very useful in an individual case, it is inconvenient if cultures continue to arrive at the laboratory at various hours of the day. Besides, some pyogenic bacteria usually get into the subculture.

The method of using picked colonies of the *Corynebacteria* from tellurite blood plates for the preparation of the bacterial suspensions, as recommended here, has the advantage of rapidity attained by the use of field cultures, combined with freedom from pyogenic microorganisms. In addition, there is the saving of labor and media by abolishing the need for subculture.

SUMMARY

A practical four-day diagnostic test for the virulence of bacilli of the *Corynebacterium* group is suggested.

The bacterial suspensions for guinea pig inoculation are prepared from colonies of the *Corynebacteria* cultured from the nose and throat swabs on blood agar potassium tellurite plates.

No false positive reactions are observed.

False negative results are avoided by the use of five or more colonies for the preparation of the bacterial suspensions.

We wish to thank Dr. Ralph S. Muckenfuss, Director of the Bureau of Laboratories of the New York City Health Department, for his advice in the preparation of this report.

TECHNIQUE AND COMPARATIVE VALUES OF CROSS AGGLUTINATION METHODS*

A STUDY OF CENTRIFUGE, SLIDE, AND HANGING-DROP TECHNIQUES

NORMAN W. HENRY, M.D., PHILADELPHIA, PA.

THE cross-matching of recipient and donor bloods necessitates the use of some procedure which allows the mixing of cells and plasma (or serum) in such a way as to be read by the naked eye or microscope. For a long time the procedure in this hospital and in many others, the hanging-drop suspension was the method of choice. Of late we have used the thirty-minute open slide procedure with entirely satisfactory results.

In their article on "Intra-group Agglutinins in Blood Transfusions," Culbertson and Rateliff compared the hanging-drop method with the rapid centrifuge method of Landsteiner and found the latter to be distinctly more sensitive. On communication with Rateliff, we have learned that in using the hanging-drop method no specific effort was made to agitate the serum-cell mixture because this was technically impractical. We suspected from preliminary observations that the hanging-drop procedure was less sensitive because of the omission from the technique of some form of agitation. Shaking or some form of agitation is an essential part of any agglutination technique, the effect being apparently to throw particles or cells together mechanically, thus facilitating agglutination.

In order to prove this suspicion the following comparative studies on the centrifuge, hanging-drop, and open slide methods were carried out. Erythrocytes (II-A) from freshly drawn or bank blood, containing approximately 0.4 per cent sodium citrate, were washed three times in normal physiologic saline and a 5 per cent saline suspension was prepared. The titer of IV-0 plasma was then determined by each of the three methods.

The open slide method consists of thoroughly mixing a drop of cell suspension with several drops of plasma (or serum) on a ringed glass slide and allowing this to stand for thirty minutes under a Petri dish. A piece of moist filter paper is placed under the dish to prevent evaporation. The cells are thoroughly agitated by twirling and tilting the slide and the preparation is observed under the microscope.

The centrifuge method consists of shaking a few drops of plasma with one drop of washed cells for a minute and then incubating at 37° C. for five minutes. This is followed by centrifuging for three minutes and reading macroscopically. The hanging-drop method is similar to the open slide method,

*From the Laboratory of the Episcopal Hospital, Philadelphia.
Received for publication, January 9, 1940.

except that a hollow ground chamber and cover slip are used and the readings are made at the end of twenty minutes *without shaking*.

The sensitivity of the centrifuge method and open slide method was observed in the following procedure: Progressive geometric dilutions of plasma with saline were prepared (up to a dilution of 1:256) in 10 mm. test tubes. An equal size drop of the washed cell suspension was placed into all the tubes. Drops from each of these dilutions were placed on open glass slides, and the technique as described above followed. The remainder of the mixture in the test tubes was treated according to the centrifuge technique. This procedure enabled us to have the identical preparation in both set-ups. The results in Table I show that both methods were equally sensitive. Readings are microscopic.

TABLE I

PLASMA DILUTION	EXPERIMENTS 1		2		3		4		5	
	C.M.	SLIDE	C.M.	SLIDE	C.M.	SLIDE	C.M.	SLIDE	C.M.	SLIDE
0	4	4	4	4	4	4	4	4	4	4
2	4	4	4	4	4	4	4	4	4	4
4	4	4	4	4	4	4	3	4	4	4
8	3	3	3	4	2	2	3	3	4	4
16	2	2	2	2	1	1	3	2	4	3
32	1	2	2	2	1	1	0	1	3	2
64	1	1	1	1	0	1	0	1	3	1
128	0	1	1	1	1	0	0	0	1	0
256	0	0	0	0	0	0	0	0	0	0

The next procedure undertaken was to determine the comparative values with reference to the hanging-drop method. In all methods the cell plasma mixtures were identical for each dilution. Results are shown in Table II. Readings are microscopic.

TABLE II

PLASMA DILUTIONS	EXPERIMENT 1			EXPERIMENT 2		
	C.M.	SLIDE	H.D.	C.M.	SLIDE	H.D.
0	4	4	3	4	4	3
2	3	4	3	4	4	3
4	3	3	2	4	3	3
8	2	3	1	4	2	2
16	1	2	0	2	1	0
32	0	1	0	1	0	0
64	0	1	0	0	0	0
128	0	0	0	0	0	0
256	0	0	0	0	0	0

In comparing all three methods, one can readily see the close relationship of the centrifuge and the open slide methods, with some inferiority of the hanging-drop procedure. In preparing the cell-plasma mixture, the centrifuge method and the slide method permit shaking or agitation, a necessary requisite for any antigen antibody reaction. Both centrifuge and slide methods permit the application of this principle. With the hanging-drop preparation agitation is technically impractical, as it causes the suspension to flow to the line of glass contact, where observation is difficult. In several instances, agglutination was observed on the open slide method before and after agitating, and the titer was seen to rise two or three dilutions as a result of agitation.

We conclude, therefore, from our observations, that the centrifuge method and the open slide method have approximately the same degree of sensitivity, and that both are superior to the hanging-drop method. The centrifuge method has the advantage of requiring less time (ten minutes, as compared to the open slide method, forty minutes). The open slide procedure, however, facilitates the study of cold agglutination and pseudoagglutination.

AN INEXPENSIVE CONSTANT TEMPERATURE PARAFFIN OVEN*

ROLAND E. MILLER, PH.D., AND ROBERT P. MOREHEAD, M.D.
WAKE FOREST, N. C.

DUE to the cost of constant temperature paraffin ovens some difficulty is experienced in obtaining a sufficient number for satisfactory operation of a technical laboratory. This difficulty has been met in our school by the construction of an inexpensive but efficient oven.

This oven consists of a wooden box, 28 inches long, 17 inches deep, and 7 inches high, which is fitted with a permanent pyramidal top tapering gradually to a height of 14 inches (Fig. 1). The oven was constructed from 1 inch pine wood and the upper pyramidal portion was lined with galvanized sheet metal to reflect the heat and to protect the wood. One side of the box is hinged at its junction with the pyramidal top so that it serves as a door, forming an opening into the oven which is approximately 26 by 7 inches.

The oven has no fixed bottom and when in use it is merely placed upon a piece of sheet tin on the table. A porcelain tray, $22\frac{1}{2}$ by $12\frac{1}{2}$ inches, serves as a container for the infiltrating work. This tray readily slides in and out of the oven and greatly simplifies embedding.

Heat is supplied by three 100 watt bulbs set in sockets at the top of the pyramid, and is controlled by a thermoregulator of simple construction. The thermostat consists of a piece of ordinary glass tubing, 30 cm. long and 5 mm. in diameter, on the end of which is blown a ball about 20 mm. in diameter. Approximately 50 mm. from the ball the tubing was bent to form a "U" tube, with a ball on one end and an opening on the other (Fig. 2). The tube was filled with mercury and then inverted. This procedure was repeated until the entire tube, except about 10 mm. at the open end, was filled. Then several drops of chloroform were added. The chloroform with a small air bubble was forced into the ball by inverting the tube. Following this, a sufficient amount of mercury was removed from the tube to lower the mercury level to about

Received for publication, January 19, 1940.

Fig. 1.—Front and side elevations showing the construction of the oven and the position of bulbs, thermostat, and relay.

Fig. 2.—A diagrammatic representation of the thermostat showing details of construction.

100 mm. from the open end. Chloroform is added because its extreme volatility between the temperatures of 55° and 65° C. causes a large variation in the height of the mercury column and therefore greater sensitivity of the instrument. The tube is then placed in the oven with the long arm extending through a small hole in the top and is so adjusted that the ball is at the approximate level of the paraffin.

Two wires were forced through a small cork and suspended in the tube. One of the wires being longer than the other was passed below the surface of the mercury, while the other remained a few millimeters above the surface. These wires were attached to a Duoco relay which in turn regulated the current supplied to the light bulbs in the oven and to a small pilot light placed on the top of the oven. By raising or lowering the wire above the surface of the mercury, it is possible to control the temperature within the oven.

The advantage to this particular type of relay is that it operates on 110 volt current, but allows only a reduced current to pass through the thermostat, thereby eliminating the necessity of batteries or an additional transformer. Furthermore, this relay is desirable because it is so constructed as to eliminate the chatter which frequently accompanies the use of alternating current in such instruments.

The total cost involved in equipping this type of oven in our laboratories has been slightly less than \$15.00 per oven. The cost of construction of the oven, including the wiring, was \$3.90, while the relay cost \$11.00. In addition to the low cost of construction the size of the oven allows a greater amount of usable space than most ovens of the same cost which generally lack the advantages of automatic temperature control.

Several of these ovens have been in use in our pathology and histology laboratories for the past year and have been found to be very satisfactory. The time required to bring the temperature in the oven to that of the melting point of paraffin, using three 100 watt bulbs, has been found to be about twenty minutes. With the door of the oven closed, the temperature, once obtained, will remain within one degree for an indefinite period.

It is suggested that following two months of continuous use the surface of the mercury should be cleaned in order to maintain the sensitivity of the thermostat. This may be easily done with a bit of cotton on the end of a small wire.

ANTIGEN PIPETTE FOR KLINE SYPHILITIC TEST*

EDWIN S. POWELL, COLUMBIA, S. C.

A STRONG and dependable pipette for use in dropping antigen in the Kline syphilitic test may easily be made from a 1 c.c. serologic pipette, 26 gauge syringe needle, rubber medicine dropper bulb, and cement ("Dart Household and General Purpose Cement" has proved most satisfactory to me).

Select a fairly stout 1 c.c. pipette—cut off a small portion of the tip so that it will fit tight in the cup of the needle. Then cut off the top of the pipette at the 0.3 c.c. mark. By cutting down the length the pipette is easier to handle. Cut off the point of the needle about 1 mm. from the joint at the bottom of the cup by notching with a triangular file and breaking it off evenly.

Place a drop of cement on the tip of the pipette and push the needle on gently and firmly. With an applicator or match stem concentrate the cement evenly around the top of the needle so as to assure permanency and no leakage. Allow this to dry thoroughly. Put the rubber bulb on the top of pipette and it is ready for use. Should there be a loose fit between the pipette and the bulb, wrap with a rubber band.

This pipette delivers approximately 62 drops per 0.5 c.c., which is the size drop Kline recommends. Because of its speed it will be found especially useful in running large numbers of tests.

A CONVENIENT TURNTABLE FOR STAINING JARS

A. BYRON LEONARD, PH.D., AND ALICE E. LEONARD, M.A.
LAWRENCE, KAN.

WHEN tissue sections are to be carried through an extensive series of reagents, a convenient arrangement of the containers is often difficult. The jars containing the reagents are often arranged in a long row, or in a series of shorter ones, but in any case the technician does not find all the jars within easy reach. However, by placing the staining jars on a turntable, such as the simple and inexpensive device described below, all the containers in a series become equally accessible to the operator.

Fig. 1 represents a sectional view of the device. In this illustration C is a circular piece of wood, $1\frac{1}{2}$ inches in thickness and 24 inches in diameter, which comprises the platform of the turntable. In the center of the ventral side of C a circular depression, 1 inch deep and 6 inches in diameter, is made to receive A, which is a pinion obtained from the transmission gears of an old

Received for publication, January 17, 1940.

automobile. The pinion *A* has a collar on its ventral side which rests within the thrust bearing *B*. The bearing *B* is held in place by being inset into the block *D*, which in turn may be secured to the top of a table. Since the bearing contains a ball race and ball bearings, the platform *C* turns very easily, even when bearing a load of Coplin jars. The cost of materials for this very convenient device was slightly more than \$1.00.

FIG. 1

FIG. 2

Fig. 2 is a perspective view of the turntable. Upon the periphery of the platform may be placed from 20 to 22 Coplin staining jars, depending upon the size of the bases. The unoccupied space in the center of the platform makes a convenient place to put the tops of the jars when the latter are in use.

CHEMICAL

A RAPID METHOD FOR DETERMINING SPECIFIC GRAVITY OF BODY FLUIDS BY THE FALLING DROP PRINCIPLE*

CARROLL J. BELLIS, M.D., MINNEAPOLIS, MINN.

CHANGES in the density of whole blood or plasma are important in defining and recognizing the onset of shock and in determining the degree of hydremia. The well-known Hammerschlag method and its several modifications (Roy, Van Walsem, Exton) are time-consuming and elaborate. Gravimetry has the same disadvantages. Since the introduction by Barbour and Hamilton^{1,2} of the falling drop method, the determination of blood specific gravity has become an acceptable routine clinical procedure. With this technique, the blood or plasma specific gravity may be determined in one or two minutes, using only a drop of the sample (0.01 c.c.), within a maximum error of ± 0.0001 sp. gr. Guthrie⁴ and Kagan⁵ have employed the falling drop principle with an accuracy far greater than clinical experience necessitates.

In the surgical wards of the University of Minnesota hospitals we have employed the falling drop method to determine the state of hydration of patients and the plasma protein concentration. After Moore and Van Slyke⁶ had formulated an expression whereby the protein concentration could be calculated if the plasma specific gravity were known, Nugent and Towle⁷ discovered that the albumin-globulin ratio had no effect on specific gravity, since albumin and globulin exerted the same effect. Weech, Reeves, and Goettsch¹² then published formulas for accurately calculating the serum or plasma protein concentration from the specific gravity. Peters and Van Slyke⁸ have indicated that of the methods for determining serum protein, the specific gravity method is sufficiently accurate. Spencer,¹⁰ after making many comparative determinations, concluded that the falling drop method was more accurate than the weight method for determining serum protein. Similarly, the later work of Shuman and Jeghers⁹ showed that detailed chemical procedures are no more accurate for routine work than the falling drop method. This communication presents a method of simplifying and accelerating the determination of blood or plasma specific gravity with the Barbour and Hamilton technique.

METHOD

From the Barbour and Hamilton alignment chart, a logarithmic progression was derived, and from an expression which designates the points on their chart, Table I was obtained. Much time is saved by using this table to obtain the apparent density differences.

*From the Department of Surgery, University of Minnesota Medical School, Minneapolis.
Received for publication, August 8, 1940.

For most samples of plasma we use the 75.3 : 24.7 :: m-xylene : bromobenzene mixture which these investigators suggested. For more hydremic or hypoproteinemic plasma the 76.9 : 23.1 mixture is used; it has a specific gravity of 1.013. If the specific gravity of whole blood is to be determined, the 72.1 : 27.9 mixture is used; this mixture has a specific gravity of 1.043. As will be recalled, the falling times of exactly 0.01 c.c. of standard solution of potassium sulfate and sample through 30 cm. of m-xylene-bromobenzene mixture are determined with the stop watch, and the room temperature is noted. Table I gives the apparent density difference of each falling drop, the apparent density difference of the standard solution being given a - sign, that of the sample a + sign. The algebraic sum of these two (actual density difference) is then algebraically added to the specific gravity of the standard solution to obtain the specific gravity of the sample. Table II (made from the formula of Weech, Reeves, and Goettsch) gives the protein concentration of the serum corresponding to the specific gravities. If plasma is used, reference to the same table may be made for clinical purposes, since the error thus produced is less than 0.5 Gm. per 100 c.c.

TABLE II
SERUM PROTEIN CONCENTRATIONS CORRESPONDING TO SPECIFIC GRAVITY

SP. GR.	PROTEIN	SP. GR.	PROTEIN	SP. GR.	PROTEIN
1.017	3.37	1.025	6.16	1.033	8.94
1.018	3.72	1.026	6.51	1.034	9.29
1.019	4.07	1.027	6.85	1.035	9.64
1.020	4.42	1.028	7.20	1.036	9.98
1.021	4.77	1.029	7.55	1.037	10.33
1.022	5.11	1.030	7.90	1.038	10.68
1.023	5.46	1.031	8.25	1.039	11.03
1.024	5.81	1.032	8.59	1.040	11.38

Example:

Temperature 22° C.

Falling time of serum = 30 sec.

Apparent density difference +0.009 (Table I).

Falling time of standard (sp. gr. 1.035) = 20 sec.

Apparent density difference -0.015 (Table I).

0.009 - 0.015 = -0.006 (actual density difference).

1.035 - 0.006 = 1.029 = sp. gr. of serum.

1.029 is equivalent to protein concentration 7.55 per cent (Table II).

COMMENT

To date, the improvement described, namely, the already calculated chart of apparent density differences, has made possible the determination of blood or serum specific gravity in a few moments. The constant checks of this method of obtaining plasma or serum protein concentration with micro-Kjeldahl readings have been both gratifying and reassuring, and it is my feeling that this method of estimating total plasma protein concentration is fully as accurate as the well-known Kjeldahl method.

The fluid requirement of the surgical patient has ceased to be an arbitrary value or a matter of "hit or miss." Closely correlated with the sodium chloride

intake and excretion is the water balance, and an index of this may be obtained by plasma density determinations. Thompson, Ravdin, and Frank¹¹ have significantly commented on the effects of hypoproteinemia on wound disruption, a relation which may be due to edema or to the general lack of essential elements which accompany low protein intake. Preoperative preparation of patients for extensive surgical procedures can be assisted by rapid protein determinations with this method. During the critical postoperative period similar determinations will indicate the general state of the patient.

SUMMARY

A successful experience with the Barbour and Hamilton falling drop method for determination of plasma, serum, or whole blood specific gravity is reported. A table is presented for use in the rapid determination of the specific gravity, and a second table is given for obtaining the serum protein concentration when the specific gravity is known. The advantages of these are mentioned, and some indications for their employment are cited.

A SIMPLIFIED SYSTEM OF BUFFERS AND INDICATORS WITH OR WITHOUT GLASS ELECTRODES*

J. F. McCLENDON, PHILADELPHIA, PA.

BECAUSE a multiplicity of technical methods are demanded in medical laboratories, there is a need for saving the time required for mathematical calculations. For this reason, I built a potentiometer reading directly in pH.⁶ A newer development is the direct reading glass electrode apparatus that eliminates all calculation in determining pH; however, it must be standardized frequently by a standard buffer because, if the proper buffer is not used, all the results will be incorrect. The following method eliminates all complicated mathematics and all errors caused by moisture in "dry" chemicals and by inaccurate volumetric apparatus used in the preparation of standard buffers. Furthermore, with a burette of uniform bore, buffers of graded series may be prepared for determining pH with indicators.

With the realization that Sørensen's values of pH were incorrect, physical chemists eliminated this criticism by coining the term "activity." Now pH is redefined as the logarithm of the reciprocal of hydrogen-ion activity. If one adds 0.04 to Sørensen's value, the correct result is obtained.

It has been shown that the ionic strength[†] of a solution affects the ionization of both indicators and buffers (salt error). But determinations of ionic strength may be avoided through the use of buffers and indicators that are affected very little by changes in ionic strength. Also calculations may be eliminated by the use of special graph paper.[‡]

An approximation should be made when these solutions are prepared. Otherwise difficulties may arise if solubilities or safe dilutions are exceeded. However, quantitative accuracy is not necessary except where indicated.

Indicators will act as buffers if they are at high concentration; hence, if they are to serve as indicators, they should be in very low concentration. Because of the low solubility of some indicators it has been customary to make their solutions 0.01 to 0.04 per cent. For uniformity of practice it is desirable to make the more soluble ones of the same concentration. Since dry indicators may not always wet with water and are more soluble in alcohol and since alcohol checks mold growth, it is well to weigh out 0.04 Gm. of the indicator, add 50 c.c. of alcohol to dissolve it (heat may be necessary), and then add 50 c.c. of water (some indicators will not completely dissolve until after the addition of water).

Methyl orange is very little, if at all, affected by ionic strength. Its "absorption" spectrum is given in Fig. 1 for both acid and alkaline solution. When light of wave length 5600 A. U. was used, the "absorption" (logarithm of

*From the Research Laboratory of Physiology, Hahnemann Medical College, Philadelphia. Aided by a grant from the American Philosophical Society.
Received for publication, December 8, 1939.

†Ionic strength = $\frac{1}{2}$ (sum of concentration of each ion \times its valence squared).

‡For sale at Hahnemann Medical College Book Shop, 235 N. 15th Street, Philadelphia.

the reciprocal of the transmittance) of the acid (un-ionized*) dye was 0.62, and the absorption of the alkaline (ionized) dye was 0.05; therefore the relative amount of the alkaline (ionized) dye may be determined. At pH 3.6 the absorption was 0.335; hence 50 per cent was ionized ($0.62 + 0.05$ divided by 2

Fig. 1—Absorption curves at 25° C. of 1 c.c. of 0.04 per cent methyl orange in 25 c.c. of N/10 HCl (tall rough curve) and N/100 NaOH (short smooth curve) made with a Coleman spectrophotometer. The ionization constant was computed from the absorption at 5600 Å. U. (0.56 μ), and pH 1, 12, and 3.6 were determined with a Coleman glass electrode. The part above 2 is not graduated since this method becomes less accurate as complete absorption is approached.

equals 0.335). Fig. 2 shows on the left the amount of yellow (a) in the dye at different pH values from 1.6 to 5.6. (The red component of the dye is represented by $1 - a$ on the right.) A similar graph for phenol red† is also shown in Fig. 2, where red component is represented by a .

*It is usually represented as a "zwitterion" or amphoteric ion, but this may be considered un-ionized since the hydrogen ion that separated at one point attached itself at another.

Phenolphthalein behaves as a dibasic acid,* and its dissociation graph appears to be a composite of the two graphs in Fig. 2. A drop of phenolphthalein solution is used in the preparation of the salt component of the buffers, but this will not interfere with the use of other indicators at pH values less than 8. Similar graphs have been prepared for a number of other indicators.^{7-9, 11, 12}

Fig. 2.—Percentage at 25° C. of methyl orange, phenol red, and phenolphthalein in the acid form (100 α , left) and alkaline form [100 (1- α), right].

STOCK SOLUTIONS

Normal hydrochloric acid: Place 10 c.c. of concentrated HCl (approximately 38 per cent by weight, 45 per cent by volume, sp. gr. 1.19) in a 100 c.c. volumetric flask and dilute to 100 c.c. Transfer to a 200 c.c. glass-stoppered bottle and add 23 c.c. of water.[†]

Carbon dioxide-free water: Place 700 c.c. of distilled water in a round bottom, liter pyrex flask. Cover with a watch glass and boil vigorously for five minutes. Insert an oversized rubber stopper and cool under tap. Allow to remain stoppered until used.

Normal sodium hydroxide: Place 75 Gm. of NaOH and 75 c.c. of water in a pyrex flask, 200 c.c. or larger. Rotate until dissolved. Transfer the hot solution to a 100 c.c. pyrex flask. Place on the surface of the liquid a lump of paraffin, which will melt and exclude air. Wrap the flask in a towel to delay cooling and let it stand until the next day when the carbonate should have settled, at least from the top layer. Lift the solidified paraffin and insert the

*Michaelis and Gyemant¹³ speak of three dissociation constants, but Kober and Marshall¹⁴ found the trisodium salt to be colorless. Rosenstein¹⁵ observed two dissociation constants.

[†]For more accurate N/10 HCl place the 1:1 acid in a still, distill off three-fourths, collect 25 c.c., and read barometer. At 760 mm. weigh out 18.017 Gm.; at 750 mm., 17.996 Gm.; at 740 mm., 17.975 Gm.; at 730 mm., 17.953 Gm.: Then dissolve and dilute to 100 c.c. (Hulett and Bonner²).

mouth end of a 10 c.c. pipette and suck up clear solution until the bulb is filled (reversal merely saves time). Run the solution into a 100 c.c. volumetric flask and fill to the mark with carbon dioxide-free water. If the flask will hold 10 c.c. more, run in 10 c.c. carbon dioxide-free water. This may be done with the same pipette, preferably without rinsing, by using a rubber tube to protect the mouth from sodium hydroxide and then sucking the solution up as far as the rubber tube to rinse the stem. Mix by inversion and rinse the pipette by sucking up several times; then transfer 10 c.c. to a small beaker or Erlenmeyer flask for titration with hydrochloric acid. Use one drop of phenolphthalein solution as indicator, and titrate to the end point, the first pink coloration that remains twenty seconds after stirring. Record the titer as 10x hydrochloric acid and add 10x carbon dioxide-free water to the 100 c.c. of sodium hydroxide on transferring to a paraffin-lined bottle. The paraffin lining is made by pouring about 20 Gm. of melted paraffin (preferably with melting point over 60° C.) into a dry 200 c.c. cylindrical, glass-stoppered bottle and rolling it on the table while cooling (having dipped the dry stopper in melted paraffin to prevent sticking with sodium hydroxide).

Normal acetic acid: Mix 6 c.c. of glacial acetic acid with 100 c.c. of water.

Normal chloroacetic acid: Weigh out 95 Gm. of monochloroacetic acid (free from acetic acid, dichlor and trichlor), and place it in a 100 c.c. volumetric flask. Add water to dissolve the acid, and fill the flask to the mark.

Normal cacodylic acid: Weigh out 13.8 Gm. of cacodylic acid, and place it in a 100 c.c. volumetric flask. Add water to dissolve the acid, and fill the flask to the mark.

CONCENTRATED BUFFERS FOR STANDARDIZING GLASS ELECTRODES

Acetic-acetate buffer: Using the same pipette so that correction for error will not be necessary, place 25 c.c. of normal acetic acid in a 100 c.c. glass-stoppered bottle and 25 c.c. in a small beaker or Erlenmeyer flask, and add one drop of phenolphthalein solution. Fill a burette with normal sodium hydroxide and run in 20 c.c.; then very carefully titrate to the first pink coloration that stays after stirring for twenty seconds. Transfer this neutralized solution (sodium acetate) to the bottle, using very small amounts of carbon dioxide-free water to rinse the titration vessel. Pour rinse water into the bottle. The pH of this 50/50 mixture of acetic acid and its sodium salt will be 4.74 at 25° C. and will remain constant on dilution up to ten times or more with carbon dioxide-free water.

Chloroacetic-chloroacetate buffer: A 50/50 mixture of chloroacetic acid and sodium chloroacetate may be made in a similar manner. The pH of this solution will be 2.86 at 25° C. (Armstrong¹ found 2.8.)

Cacodylic-cacodylate buffer: A 50/50 mixture of cacodylic acid and sodium cacodylate may be made in a similar manner except that the titration should not be stopped at a pale pink but continued to maximum color. The pH of the 50/50 mixture will be 6.2 at 25° C.

Borax buffer: A solution of borax may have a pH of 9.15 to 9.2, but its pH is influenced by the ionic strength and therefore is changed by dilution. Its advantage lies in the fact that no titration is necessary. The use of carbon

dioxide-free water in dissolving it is imperative, and its solution must be protected from the carbon dioxide of the air.

PREPARATION OF A GRADED SERIES OF BUFFERS FROM pH 2 TO 8

The titration graph of one of the acids listed above with sodium hydroxide using a glass electrode as indicator gave the clue for the preparation of buffers of any pH within its range. But it is not necessary for each investigator to make this titration graph over again. By using the special graph paper (Fig. 3) the titration graph becomes a straight line running through the pH value of the 50/50 buffer at its midpoint and a point 2 pH units to the left at the lower margin. The unit denoted by α on the left margin denotes the fraction of the acid neutralized by sodium hydroxide. Because this titration graph assumes that the free acid is undissociated, it cannot be used for any but very low concentrations of hydrogen ions, certainly not for pH less than 2.

Fig. 3.—Titration graphs at 25° C. of chloroacetic, acetic, cacodylic, and boric acids. The fraction neutralized is represented by α on the left. Hitchcock and Taylor give slightly different values. The boric curve on the left assumes borax as completely, and on the right, as half neutralized.

From Fig. 3 it is seen that cacodylic acid covers the pH range from 4.2 to 8.2. In order to make a buffer of any pH within this range without calculations it is necessary for the "normality" of the normal sodium hydroxide and the cacodylic acid to be exactly equal. Therefore, pipette 10 c.c. of cacodylic acid into a titrating vessel, add one drop of phenolphthalein solution, and titrate with the sodium hydroxide to the maximum color that remains twenty seconds after stirring. Read the burette, and if 11 c.c. (for instance) have been required, add 10 per cent distilled water to the remainder of the cacodylic acid; if 9 c.c. (for instance) have been required, add 1 c.c. of water to each 9 c.c. of sodium hydroxide solution.

To prepare any buffer between pH 4.2 and 8.2 trace the pH coordinate to the cacodylic acid graph and note the α coordinate that it intercepts. If x represents the number of cubic centimeters of cacodylic acid chosen, add αx cubic centimeters of sodium hydroxide solution. Similar procedures may be made with acetic and chloroacetic acids.

Boric acid behaves in a peculiar manner (Fig. 3). If we assume boric acid to be monobasic and titrate normal boric acid with normal sodium hydroxide, a straight line from about pH 8.8 to 10.2 is obtained, with pH 9.15 representing half neutralization (as borax). But if we assume borax to be the fully neutralized "salt," then boric acid is only half monobasic, and when it is titrated with 0.5 normal sodium hydroxide, the straight line from about pH 6.5 to 8.8 is obtained. This abnormal behavior, together with the sensitivity of borate buffers to ionic strength and the rapidity with which they absorb carbon dioxide from the air, makes the use of borates undesirable.

Fig. 4.—Ionization graphs at 25° C. of the amino acids of protein hydrolyzates. *A*, aspartic acid; *h*, histidine; *G* (double line), glutamic and hydroxyglutamic acids; *a*, arginine; and *l*, lysine. The ionization graphs of the amino groups slope in the opposite direction to those of the carboxyl groups.

BUFFER ACTION OF AMINO ACIDS

In attempting to buffer solutions containing protein hydrolytic products one should bear in mind that they themselves have a powerful buffer action, as shown in Fig. 4. In this chart aspartic acid is marked *A*; glutamic and hydroxyglutamic, *G*; histidine, *h*; arginine, *a*; and lysine, *l*. The dissociation graphs of the other amino acids are so close together as to make labeling difficult. On the addition of any buffer composed of partly neutralized acid, the acid would partly combine with the amino groups of these amino acids and the base would distribute itself between the carboxyl groups of these amino acids and the

Fig. 5.—Carbonic acid-bicarbonate graph at 38° C. On the left is marked the bicarbonate on the right, the partial pressure of carbon dioxide necessary to produce the pH given at the bottom.

Fig. 6.—Graph of relation at 38° C. between the concentration of bicarbonate in millimoles per liter, the pressure of carbon dioxide in millimeters of mercury, and the pH. The smaller triangle on the right is enlarged on the left to emphasize the physiologic range. The graph on the right starts at 1 mm. carbon dioxide pressure: the atmospheric pressure is about 0.2 mm. Whenever Ringer's fluid, for instance, containing bicarbonate is in contact with living tissue, the carbon dioxide pressure tends to be higher than atmospheric, and perhaps the range is sufficient for ordinary laboratory conditions.

added buffer acid. It is much simpler to use the buffering power of the amino acids themselves, adjusting the pH by additions of sodium hydroxide (or hydrochloric acid) with the aid of an indicator or glass electrode. In this chart the amphoteric ions (zwitterions) are represented as undissociated molecules since they do not affect the pH although they do affect the ionic strength.

BICARBONATE BUFFERS

Just as borate buffers may change by absorption of carbon dioxide from the air, bicarbonate buffers may change by loss of carbon dioxide to the air and can be preserved only if they are kept under a fixed partial pressure of carbon dioxide. Fig. 5 is a graph at 38° C. of pH of bicarbonate solutions of concentration shown on the left margin; pressure of carbon dioxide is given on the right margin. This graph is limited, however, by the fact that there is only one pressure of carbon dioxide for each concentration of bicarbonate. To extend the range the triangular form of graph shown in Fig. 6, right, may be used with the physiologic range enlarged at the left.*

THE MEASUREMENT OF THE CHLOROFORM-SOLUBLE FRACTION OF BILIRUBIN IN PERSONS WITH JAUNDICE AND ITS SIGNIFICANCE*

NORMAN HEILBRUN, M.D., AND ROGER S. HUBBARD, PH.D.
BUFFALO, N. Y.

IT IS well known that the bilirubin in serum or plasma of patients with obstructive or hepatogenous jaundice gives a different reaction with diazotizing (van den Bergh) reagents from that given by bilirubin in specimens from persons with acholuric jaundice.¹ This can be demonstrated by noting the speed with which a color appears after the reagents and serum are mixed. It has been postulated that the difference in the reaction is due to two different types of bilirubin, but the underlying chemical or physicochemical causes of the difference have not as yet been definitely determined. That both types of pigment are present in some cases of jaundice has been suggested by some investigators.² In a recent paper we showed that an interpretation of the so-called biphasic van den Bergh reaction obtained when both pigments are present is often very difficult.³ It seemed desirable, therefore, to investigate another method of distinguishing between the two forms of bilirubin.

Many years ago Grunenberg⁴ observed that the bilirubin was wholly soluble in chloroform in persons who gave an indirect, slow van den Bergh reaction. Since this report attempts at the separation of two types of bilirubin in the serum by means of chloroform have been made by Varela and his co-workers,^{5, 6} and more recently by Greene and associates.⁷ The former workers studied various types of jaundice, especially the hepatogenous and the obstructive groups, and commented upon the different amounts of the chloroform-soluble fraction. In their analyses the chloroform-soluble portion was concentrated by evaporation after extraction, redissolved in alcohol, and diazotized. The residue which contained the water-soluble or direct-reacting portion was also diazotized, and the sum of the two fractions then gave the total amount of bilirubin in the serum.

In trying to repeat this work according to their technique we encountered certain difficulties. The diazotization of the two fractions did not always yield colors that could be easily compared with that of the cobalt standard. This same difficulty has been commented upon by many workers who have used the van den Bergh reaction, and various modifications of the test for avoiding the difficulty have been proposed. We tried several of these but found that they were not completely satisfactory. Our preliminary experiments showed that slightly acidified solutions of pure bilirubin in chloroform could be accurately quantitated by comparison with the 1:6,000 water solution of potassium di-

*From the School of Medicine, University of Buffalo and the Buffalo General Hospital.
Received for publication, December 27, 1939.

chromate standard used by Ernst and Förster.⁸ Since this method did not involve diazotization, the difficulty mentioned was avoided.

When the yellow chloroform-soluble pigment was concentrated according to the technique of Varela and his co-workers, and redissolved in chloroform and alcohol to a definite volume, it was found on comparison with the dichromate standard, both before and after concentration, that there was a loss of approximately 50 per cent of the yellow color. Because of this it was decided not to concentrate the extract but to use a direct comparison between the yellow color given by the chloroform-soluble pigment and the dichromate standard. The accuracy of this determination was checked in two ways: first, by measurement of the color of known amounts of bilirubin dissolved in chloroform as previously mentioned; second, by demonstrating the quantitative recovery of injected bilirubin. For this bilirubin was injected into normal persons or those with hypochromic anemia. Samples of blood were taken both before and within three to five minutes after the injection. The quantity of bilirubin found in the chloroform extract of the sample after injection compared closely with the total increase of the bilirubinemia as estimated by the quantitative van den Bergh test. When such samples were tested with the qualitative van den Bergh reaction, it was found that the reaction was always of the indirect or delayed type. The results of these experiments have been described in a previous paper.³

The study of a group of patients with increased bilirubinemia due to various causes selected from the services of the Buffalo General Hospital is presented here. All specimens of sera or plasma were subjected to chloroform extraction, and the total amount of the chloroform-soluble bilirubin fraction was estimated. The bilirubin in a second portion of the serum or plasma was determined quantitatively by the Thannhauser and Andersen method.⁹ The relationship between the quantity of the chloroform-soluble or indirect-reacting bilirubin and the total amount were charted in an attempt to see whether there were any correlations between the various types of jaundice, and whether the obstructive or hepatogenous groups could be separated from one another. The latter, from a clinical point of view, would be very desirable.

The technique for the estimation of the chloroform-soluble fraction, which can be employed even in the presence of a moderate degree of hemolysis, is as follows: 1 c.c. of the serum or plasma is placed in a centrifuge tube. Three to 4 c.c. of chemically pure chloroform is then added. The tube is capped with the thumb and shaken vigorously for twenty to thirty seconds. It is then centrifuged for two to three minutes. The lower yellow chloroform layer is transferred to a graduated 15 c.c. centrifuge tube. This is done with a fine-tipped pipette inserted through the upper thick layer down to the bottom of the tube. Extraction is repeated until the chloroform remains colorless. Each successive fraction is added to the original in the graduated tube. Usually two or three extractions will remove all of the soluble pigment; occasionally, five or six are necessary. The total amount of chloroform-soluble bilirubin is now estimated in the following manner: The total quantity of the pooled fractions in the graduated tube is noted. Turbidity is rarely present, but when it is it can be cleared by placing the tube in a warm water bath for a few seconds. A small portion of this is now removed, and its color is compared

with that of the 1:6,000 potassium dichromate solution in a microcolorimeter with cups of a capacity of 1 to 2 c.c. The following calculation was derived from our experiments, and is the same as that which Soffer¹⁰ used in the bilirubin excretion test in which acetone is employed as the solvent:

$$\text{Total amount of CHCL}_3 \times \frac{\text{Reading of standard}}{\text{Reading of unknown}} \times 0.329 = \text{Milligrams of bilirubin per 100 c.c.}$$

The patients studied have been arbitrarily divided into the following groups: (1) hepatogenous jaundice, which included so-called catarrhal jaundice, acute yellow atrophy, portal cirrhosis, toxic hepatitis due to arsphenamine, toxic hepatitis accompanying overwhelming bacterial sepsis; (2) obstructive jaundice due to common duct stone, carcinoma of the head of the pancreas, obstructive biliary cirrhosis; (3) mild jaundice accompanying chronic passive congestion; (4) hemolytic jaundice, including congenital acholuric jaundice, pernicious anemia and allied states, mild jaundice accompanying malarial therapy for syphilis of the central nervous system; (5) two patients who fall in the group described by Rozendaal, Comfort, and Snell¹¹ as functional jaundice which gives the indirect van den Bergh reaction. Some persons in most groups were studied by successive determinations through the course of the disease.

TABLE I

	GROUP	NUMBER OF DETERMINATIONS	AVERAGE VALUE OF TOTAL QUANTITY OF CHLOROFORM-SOLUBLE BILIRUBIN (MG./100 C.C.)	AVERAGE PERCENTAGE OF CHLOROFORM-SOLUBLE PIGMENTS TO THE TOTAL QUANTITATIVE VAN DEN BERGH TEST (PER CENT)
I	Hepatogenous	74	0.89	24.0
II	Obstructive	38	0.68	27.9
III	Chronic passive congestion	54	0.64	61.0
IV	Hemolytic	34	1.07	74.0
V	Functional	4	1.11	86.7

The average values of the chloroform-soluble portion and the average percentage of the total amount of bilirubinemia which it forms have been estimated for the various groups and recorded in Table I. In addition, the individual values for each specimen studied have been charted according to their frequencies. One chart records the total quantity of the chloroform-soluble fraction and the other records the percentage which it forms of the total amount of bilirubin as estimated by the quantitative van den Bergh reaction. Each dot represents a single determination.

COMMENT

It will be noted from Table I that there is little difference between the average values for the patients grouped under "hepatogenous" and "obstructive" jaundice. This is true both for the chloroform-soluble fraction and for the percentage which it forms of the total bilirubin. Any attempt to separate these two clinical conditions on the basis of these average values would not

seem to be justified. Furthermore, many persons in both groups with a high degree of bilirubinemia had relatively small amounts of chloroform-soluble bilirubin when compared with the total amount present. Nevertheless, even though this amount was a small proportion of the total, it was considerably greater than that found as a result of normal red blood cell destruction. If one considers the usual amount of bilirubin in the blood stream a result of the balance between normal red blood cell destruction and the ability of the liver to remove it, then the accumulation of it in the blood stream in the absence of increased red blood cell destruction should be some indication of the functional state of the liver. If this is true, then the measurement of the chloroform-soluble or indirect-reacting pigment in cases of severe jaundice may be regarded as an estimation of liver function. In essence, this would seem to be the same measure of function as that utilized in von Bergmann's¹² bilirubin excretion test, but this proposed chloroform method can be applied when jaundice is present.

Chart L.—Percentage which the chloroform-soluble bilirubin forms of the total quantity of bilirubin as estimated by the quantitative van den Bergh reaction. Each dot represents a single determination.

Some persons had values of chloroform-soluble pigment, ranging from 1.5 to 3.5 mg. per 100 c.c., which amounted to only 15 to 30 per cent of the total amount of bilirubinemia. However, this quantity of pigment is three to six times the amount normally found, and, in our opinion, indicates an impairment of the ability of the liver to perform its normal excretory function. Furthermore, the frequency charts show that greater numbers of the higher values of the chloroform fraction occur in the hepatogenous group. It would seem reasonable that this should be so because it is in this group that the pathologic process involves the liver cells diffusely, and one should expect that the function of excreting the bilirubin derived from the breakdown of red blood cells would be impaired to a greater degree in this group than in obstructive jaundice where the primary process does not involve the liver cells directly. We feel that this confirms our belief.

That both fractions are present in persons with severe jaundice of this nature has been commented upon only recently.¹³ That their presence was not recognized earlier when the qualitative van den Bergh test was done in the usual way resulted from the fact that the immediacy of the reaction is so marked in the presence of a relatively large amount of direct-reacting pigment, that the slowly progressive reaction of the indirect pigment is obscured.³

In the groups of persons with chronic passive congestion it is seen that the greatest portion of the total amount of bilirubin is chloroform soluble. In some cases the pigment was wholly of this type, and this was usually so when the congestion was at its height. Again it would seem reasonable to consider that the function of a markedly congested liver is impaired. It may be argued that some of the bilirubinemia resulted from the breakdown of infarcts. However, in two persons with rather high values subsequent autopsy showed no evidence of infarction, either recent or old. This increase of the chloroform-soluble pigment is also in accord with the fact that most of the cases give an indirect or biphasic van den Bergh reaction. We studied this latter reaction and found it to be the result of the combination of a relatively large amount of indirect-reacting pigment with a small amount of direct-reacting pigment.³

Chart 2.—Total quantity of chloroform-soluble bilirubin in each specimen. Each dot represents a single determination.

Those persons whose jaundice was due to excessive hemolysis were found to have the greater portion of the total amount of bilirubin in the chloroform-soluble form as seen in Table I and Charts 1 and 2. This coincides with the frequent observation that they give a delayed or indirect van den Bergh reaction. However, if the concentration of the total pigment is relatively high, a prompt color development may be noted upon addition of the diazotizing reagent, but this is always of the slowly progressive type, requiring fifteen to thirty minutes to reach its maximum intensity.

The cases in the last group of functional disability of the liver show the greatest portion of the pigment to be soluble in chloroform. This also conforms with the observed indirect van den Bergh reaction.

CONCLUSIONS

1. A convenient and simple method for determining quantitatively the solubility of bilirubin in chloroform has been described.
2. This method is applicable to the measuring of the so-called indirect or delayed-reacting pigment in persons with jaundice.
3. It is suggested that a measurement of this portion may serve as an index of the potential capacity of the liver when jaundice is present and when excessive hemolysis is absent.

A SIMPLIFIED CONTINUOUS EXTRACTOR FOR ESTROGENS AND ANDROGENS*

DONALD WILSON, PH.D., ROBERT C. GRAUER, M.D., AND
ELEANOR SAUER, B.S., PITTSBURGH, PA.

THOROUGHNESS in the extraction of urine being the first essential for the proper assay of a given specimen, we have developed a continuous extractor which embodies simplicity with economy without sacrificing efficiency. The extractor was designed on the basic principle of that employed by Koch¹ in his much larger extractor. It consists of an all-glass apparatus made up of five units; a round bottom flask with a $\frac{40}{35}$ joint which can be made interchangeable with flasks of various sizes, an Erlenmeyer liter flask of heavy glass suitable for vacuum work, an ordinary Hopkins condenser, a side arm and upright portion connecting the first three mentioned units, and a filter tube containing a sintered glass bottom. The various measurements of the apparatus† are given in Fig. 1. The extractor can be used singly or in a battery of as many units as is desired. We found that a battery of four extractors makes a

*From the Endocrine Laboratory of the Elizabeth Steele Magee Hospital and the Department of Research in Endocrinology and Metabolism of the William H. Singer Memorial Research Laboratory of the Allegheny General Hospital, Pittsburgh.

Received for publication, December 11, 1939

†This unit can be secured from the Scientific Glass Co., Bloomfield, N. J.

practical set-up and that if necessary multiple batteries of four each can be placed in position, each battery facing another. To facilitate working with a battery, an extractor rack was designed from $\frac{3}{8}$ inch gas pipe to which a vacuum line, water line, and overflow line for the water were permanently attached. Each unit was connected separately to its own three lines, and the vacuum was connected with a common vacuum pump. An adjustable bar which can be raised or lowered holds the clamp that fastens the round bottom flask securely. A battery of four extractors occupies a space 26 inches in width and only 22 inches in depth, including the space occupied by the electric hot plate,* which is long enough for four flasks. Figs. 2 and 3 give the details of design and show the compactness of the battery.

CONTINUOUS EXTRACTOR

Fig. 1.—Details of construction extractor.

The methods employed in our laboratories are modifications of generally accepted methods.^{2,3} The apparatus can be used for the extraction of both estrogens and androgens. Seven hundred and fifty cubic centimeters of previously hydrolyzed urine are placed in the round bottom flask, and a like amount of benzene is introduced into the Erlenmeyer flask which is placed on the hot plate. By using a vacuum we were able to speed up the volatilization of the benzene and thus hasten the extraction. The side arms and the inner filter tube are arranged so that all of the volatilized and condensed benzene must pass through the urine that is being extracted. The incline on the distal arm of the

trap aids siphoning of the condensed benzene back into the Erlenmeyer flask and a continuous process proceeds. The sintered glass on the filter tube acts as a diffusing medium so that a maximum amount of contact between the benzene and urine ensues.

Fig. 2.—Details of construction of extractor rack.

It has been suggested⁴ that approximately twelve volumes of benzene should be passed through the urine to be extracted in order to secure the maximum yield. It has further been observed that for androgenic extraction a shortening of the period of extraction is productive of a higher yield.^{5, 6} In the case of extraction for estrogens this does not appear to be a factor, the preliminary length of hydrolysis appearing to be the determining point in the yield.⁷ Nevertheless, whether estrogens or androgens are being extracted, the ability to complete an extraction during the working hours is important. Where inflammable or explosive materials are being used, the fire hazard is too great to allow an extraction to proceed throughout the night. We computed that seven liters of benzene can be passed through the urine in eight hours so that ten volumes of benzene, considering volume for volume, can be passed through the hydrolyzed urine. While the reduction of the time is not a factor in the quantitative yield of estrogen, it is definitely an important factor in producing a higher androgenic yield.

Fig. 3.—Photograph of extractors and extractor rack arranged as a battery of four extractors.

CONCLUSIONS

1. A simplified, economical, and efficient continuous extractor for estrogens and androgens is described.
2. An extractor rack to permit economy of space in arranging batteries of extractors is illustrated.
3. The principle of safety and efficiency in extraction is emphasized.

THE DETERMINATION OF CALCIUM IN URINE*

A. E. SOBEL, B.S., CH.E., M.A., PH.D., AND B. A. SOBEL, B.CH.E.
BROOKLYN, N. Y.

THE estimation of calcium in the urine is usually more difficult than the estimation of serum calcium. This is due to the tendency of urates and other organic materials to coprecipitate with the calcium oxalate precipitate and thus interfere in the subsequent oxidimetric titration. By employing the direct acidimetric titration principle,^{1, 2} it was found that excellent results may be obtained in urine without resorting to ashing. In this procedure the calcium oxalate is converted to the carbonate or to the oxide by heat, which causes the decomposition of any adsorbed urates or other organic materials. To prove this point, comparison analyses were performed on urine, both directly and upon hydrochloric acid solution of the residue obtained by dry ashing. To prevent coprecipitation of magnesium and eliminate any possibility of phosphate precipitation, the pH of the solutions was adjusted to from 3.0 to 3.3 for precipitation of the calcium oxalate. The results are shown in Table I. Each value is the mean of two or more analyses on the same solution.

TABLE I

COMPARISON OF CALCIUM VALUES OBTAINED ON ASHED AND UNASHED URINE
(VALUES EXPRESSED IN MILLIGRAMS OF CALCIUM PER 100 ML. OF URINE)

UNASHED	ASHED
9.15	9.15
11.70	11.75
4.14	4.12
12.0	12.05
4.02	3.98
4.26	4.32

METHOD

For urine specimens without sediment. Two to 4 ml. of urine are pipetted into a 15 ml. pyrex ungraduated centrifuge tube. One milliliter of saturated ammonium oxalate is added. A drop of 0.04 per cent thymol blue indicator is added, and the pH is adjusted to from 3.0 to 3.3 by the use of 6 normal

*From the Pediatric Research Laboratory and the Division of Biochemistry, the Jewish Hospital of Brooklyn.

Received for publication, February 1, 1940.

hydrochloric acid and ammonium hydroxide. The solution is allowed to stand for three hours. From this point on the method follows exactly that of Sobel and Sklersky for blood serum.¹ The oxalate is converted to carbonate by heating at 475° to 525° C. The carbonate is then dissolved in a hot 10 per cent boric acid solution and directly titrated with 0.01 N hydrochloric acid.

For urine specimens with sediment. In some urines, and in all urines after standing, a precipitate appears. This can be cleared up by boiling a representative sample of the urine plus sediment, or the entire specimen if the sediment is coarse-grained, preventing a representative sample from being taken, with concentrated nitric acid in the proportions of 10 ml. of acid to 50 ml. of urine. After boiling to one-half the original volume, the digest is diluted to known volume and a sample is analyzed as above.

Preparation of ashed urine specimens. To compare the calcium values obtained on ashed urine specimens to that of unashed urine, the following technique was employed: twenty-five milliliters of urine are pipetted into a platinum dish. The liquid is then evaporated off on a steam bath or in an oven at 100° C. overnight. The residue is then ashed in an oven at 500° to 600° C. until white. The ash is dissolved in 6 N hydrochloric acid and transferred quantitatively to a 25 ml. volumetric flask. Two milliliters of this solution are then used for analysis.

CONCLUSION

The direct acidimetric titration method for calcium is applicable to urine without ashing. This simplifies the methods for determining calcium in urine.

THE SHORT PHENOLSULPHONEPHTHALEIN TEST OF RENAL FUNCTION*

MILTON PLOTZ, M.D., F.A.C.P., AND MARGARETHE ROTHENBERGER, M.D.
BROOKLYN, N. Y.

WITH THE TECHNICAL ASSISTANCE OF EDGAR FERGUSON, B.S.,
AND VICTOR GINSBURG, M.D.

IT MAY be safely stated that at the present time there is no altogether satisfactory test of kidney function. There is reason to believe that moderate or even advanced renal lesions may produce no modification in kidney function tests and that a kidney which is normal in every way may on occasion give a deceptively low reading. Evaluation of the patient's renal status means a consideration of his history, physical examination, examination of urine, blood, ocular fundi, and other routine examinations as well as the application of certain renal function tests. All the data must be considered and all the evidence weighed before any final judgment can be made and, even then, it must usually be made with caution unless the disease process is advanced. Don's conclusions, after using several different methods of testing renal function on 63 patients, is worth quoting.¹ "The lack of parallelism between the tests especially in the lesser grades of renal damage, was most disappointing. None of them appear to be capable of enabling the clinician to give a very much more accurate prognosis than is possible from the knowledge of the blood urea alone. However, if any of the tests show marked loss of renal function in the absence of a raised blood urea it would probably be best to give a guarded prognosis. A re-examination of the patient in three months might help; clinical examination will often furnish very valuable information and must still be regarded of the foremost importance. To conclude, the failure of the tests to agree closely with one another suggests either that they are not completely reliable or that different renal functions are being measured."

In view of the fact, therefore, that no one test of kidney function can provide a short cut to diagnosis, it seemed desirable to find one of the numerous tests now available which could be applied with a minimum of technical equipment and experience, with as little consumption of time as possible and would yet correlate fairly closely with more cumbersome methods. The criteria for a test of this sort seemed to be met by the fractional phenolsulphonephthalein test popularized by Chapman,² which can be completed in half an hour, requires a minimum of apparatus and reagents and can be used as a simple office procedure if necessary. Genitourinary surgeons have until very recently utilized the phenolsulphonephthalein test to a far greater extent than have internists, and it was they who first called attention to the importance of the

Clinical studies in renal disease No. 5 from the Long Island College of Medicine.

Received for publication, February 3, 1940.

early excretion of the dye.³ More recently, MacKay and Rytand have written: "The phenolsulphonephthalein test is superior to the blood urea concentration as a measure of the amount of functioning renal tissue."⁵

In an effort to repeat and confirm Chapman's experiments and to establish a series of satisfactory normals, the following project was carried out on the medical wards of the Kings County Hospital. Two hundred and three cases were studied in detail, of which 109 had obvious kidney damage. The fractional phenolsulphonephthalein test was correlated with the two-hour phenolsulphonephthalein, urea clearance, concentration tests, studies of nitrogen retention in the blood, and clinical data, although not all tests were done in every case. A detailed study of the sodium ferrocyanide test, as proposed by Stieglitz, was done simultaneously and has already been reported in detail in a separate paper.⁴

The technique of the test suggested by Chapman was followed by us with occasional modifications to be noted. The patient voids in the morning and drinks two glasses of water, noting the time. This may be done before reporting, but it is best to perform the entire test in the laboratory or office. One-half hour later 1.0 c.c. (6.0 mg.) of phenolsulphonephthalein solution is injected intravenously, and exactly fifteen and thirty minutes later the patient voids and the urine is collected. For the purposes of this experiment, one- and two-hour specimens were also collected, but this is unnecessary for routine examinations since no additional information is obtained by prolonging the test period. For use in the physician's office, when saving time is important, the total test period can be shortened from one hour to one-half hour in the following manner: When the patient arrives, give him two or three glasses of water to drink at the same time the injection is made and collect only the half-hour specimen if the patient cannot urinate at the end of fifteen minutes. The results are somewhat improved if the patient is told to drink a glass of water before leaving home. He should not void before the dye is given. We have found no significant differences between the two methods.

Vallery-Radot and his colleagues⁶ were favorably impressed by the short test and have abandoned longer procedures. In their tests all normal patients excreted 25 per cent or more within fifteen minutes. Readings of 15 per cent or less indicated some degree of failure of kidney function in almost all cases. They considered readings of about 20 per cent to be equivocal and repeated the tests. Part of the purpose of our experiment was to check these figures and to establish satisfactory normals for phenolsulphonephthalein excretion, and while we are not as yet wholly satisfied about this aspect of our work, we feel that our criteria are sufficiently accurate for most clinical purposes.

Normals.—One hundred and twenty-three short phenolsulphonephthalein tests were performed on 103 adult patients thought to be clinically free of renal disease or hypertension. In fourteen instances the phenolsulphonephthalein excretion after fifteen minutes was less than 25 per cent. In eight of these, one or more confirmatory tests (urea clearance, blood urea, ferrocyanide excretion) supported the conclusion that there was, temporarily at least, some impairment of renal function. It is possible, of course, that some of these patients will go on to clinical renal disease and that in any group of hospital patients presumably free of kidney involvement a small percentage would show some

changes in renal function tests. Of the remaining six patients, one showed a normal reading on repetition of the test. In five cases (4.9 per cent), in which there was no supporting evidence of renal impairment, the phenolsulphonephthalein readings were subnormal. The test gave a slightly higher percentage of normal figures in normal patients than any of the other tests, urea clearance, concentration tests, ferrocyanide clearance, blood urea, and two-hour phenolsulphonephthalein. In no case where the figure was low did the two-hour phenolsulphonephthalein test reveal normal figures. In two cases the figures were below normal for the quarter-hour excretion but were normal for the thirty-minute period.

Kidney Disease.—There were 21 cases of definite kidney impairment. The diagnoses in all cases were either chronic glomerulonephritis or nephrosclerosis. No tests were performed on patients with acute kidney disease. The fifteen-minute phenolsulphonephthalein test was 20 or below in nineteen of these. In one of the two others the figure was 22 per cent and in the other it was 25 per cent. In the former case 74 per cent of the dye was excreted in two hours. In the latter, the fifteen-minute figure was apparently normal but very little more dye was excreted in two hours, the total for that period being 35 per cent. The urea clearance was constantly diminished in all cases.

Hypertension.—There were 26 persons with early to moderate hypertension without clinical evidence of cardiac or renal failure. In eight of these the fifteen-minute phenolsulphonephthalein test showed diminished excretion. In only five was the urea clearance reduced below normal limits. This series is, of course, too small to be of much value, but it would seem to indicate that this test is a fairly sensitive method of detecting early renal changes in hypertension.

Congestive Heart Failure.—There were 20 patients with congestive heart failure. In all but two of these, during the stage of congestion there were low figures which improved as the cardiac function returned to normal. The urea clearance and the ferrocyanide excretion were correspondingly diminished. The blood nitrogen levels were not as consistently affected. Urine concentration tests were of little value during congestive heart failure.

There are few precautions needed in making or interpreting this kidney function test. We observed no reactions to the intravenous use of this dye, although Vallery-Radot, while temporarily using a somewhat different technique, did observe some. In the presence of liver damage the excretion is somewhat in excess of what one would expect, and borderline results should be interpreted conservatively and repeated. The explanation of this phenomenon probably lies in the fact that the liver usually excretes a portion of the phthaleins in the body through the biliary tract, and when there is failure of this mechanism, higher amounts appear in the urine. We have no experience with the test in uncomplicated anemia, but Chapman maintains that there is no significant effect of the latter on phenolsulphonephthalein excretion.⁷

Catheterization was rarely necessary. If the patient did not void after fifteen minutes, an extra glass of water was given and only the thirty-minute specimen was collected with little or no impairment of the test's value. Catheterization is, of course, an objection to any test which is to be used as an office procedure, but it may be necessary in prostatic enlargement or other conditions

in which there may be residual urine. The phenolsulphonphthalein test shares this disability naturally with any test which depends on the measurement of urinary constituents and is, therefore, necessarily limited in usefulness in cases of urinary retention. It should be noted that Macht⁸ maintains that phenolsulphonphthalein elimination may be delayed after the ingestion of magnesium sulfate for a period of as long as three to four hours. We have no experience with this.

Stieglitz⁹ cautions that "In rare instances some metabolic quirk causes chemical destruction of the dye within the body. If the urine contains no dye after injection, this is then no proof of renal failure." We have had no such experience but the caution should be borne in mind.

CONCLUSIONS

The short phenolsulphonphthalein test has been a very valuable aid to clinical diagnosis in our hands. The two-hour period has no advantage over the shorter periods. The positive value of the test is greater than its negative value. In other words, one is safe in saying that a patient who excretes 25 per cent or more phenolsulphonphthalein within fifteen minutes after its administration, or more than 35 per cent within thirty minutes, has normal kidney function. On the other hand, failure to secrete this amount has less diagnostic value. Borderline cases (17 to 24 per cent in fifteen minutes or 25 to 34 per cent in thirty minutes) should be evaluated with caution or the test should be repeated. Although definitely low reading almost surely means impaired kidney function at the time of the test, low readings should not be allowed to supersede clinical judgment.

SUMMARY

1. The difficulties of measuring renal damage by means of kidney function tests are described.
2. The short phenolsulphonphthalein (P.S.P.) test takes a half hour or less and is extremely useful. It is simple, requires a minimum of technical skill and equipment, and may be used as an office procedure. The two-hour phenolsulphonphthalein test has no advantages over the shorter test.

DEPARTMENT OF ABSTRACTS AND REVIEWS

ROBERT A. KILDUFFE, M.D., ABSTRACT EDITOR

SULFAPYRIDINE, Effect of Sulfanilamide and, on Hemoglobin Metabolism and Hepatic Function, Watson, C. J., and Spink, W. W. Arch. Int. Med. 65: 825, 1940.

Sulfanilamide in customary therapeutic doses usually causes acceleration of the metabolism of hemoglobin characterized by an increase of urobilinogen in the feces and a varying increase in the reticulocyte percentage. The most marked acceleration of hemoglobin metabolism is represented by the unusual cases in which outspoken hemolytic anemia occurs. This condition is therefore to be regarded as a much more marked degree of a usual toxic effect of the drug. Limited data indicate that sulfapyridine has the same effect as sulfanilamide on hemoglobin metabolism.

The occurrence of macrocytic or normocytic, mildly hypochromic anemia after administration of sulfanilamide or sulfapyridine indicates a disturbance in hemoglobin formation in addition to increased hemolysis.

In many persons the administration of sulfanilamide in the usual doses is followed by some evidence of dysfunction of the liver, such as urobilinogenuria, elevation of the serum bilirubin, or outspoken jaundice. The last-mentioned condition is in part of the regurgitation type, as is evidenced by the frequent occurrence of a direct van den Bergh reaction. Sixteen cases of jaundice following sulfanilamide therapy have been encountered. But one instance has been noted in which jaundice followed use of sulfapyridine. Administration of sulfapyridine resulted in an elevation of the serum bilirubin in two cases in which frequent determinations were made before, during, and after administration of the drug. This is in contrast with the results in the group treated with sulfanilamide, in which significant elevation of the serum bilirubin was usual. Although the data on sulfapyridine are as yet too limited to permit definite conclusions, there is reason to believe that this drug may not be as disturbing to hepatic function as is sulfanilamide.

CARCINOMA, Cutaneous, Diagnosed Clinically Without an Autopsy. Result of Treatment in a Consecutive Series, Warren, S., Simmons, C. C., and Rea, S. L. J. A. M. A. 114: 1619, 1940.

Of 829 treated carcinomas of the skin not verified by biopsy, 84 per cent were followed for five years. There were 57 per cent three-year cures and 48 per cent five-year cures of all the tumors treated. If the cases lost and dead of intercurrent disease are counted as cures, the five-year cures would be 84 per cent; if they are entirely excluded, the percentage would be 76. Recurrences occurred in 13 per cent of cases showing primary healing followed one year or more.

Primary healing occurred in 94 per cent of the lesions followed one year or more. More than one-fourth of the deaths from cutaneous carcinoma occurred after primary healing; primary healing should not be considered a criterion of cure.

Failures are due largely to the use of very light filtered radon applied to the surface in inadequate dosage. X-rays or radium used at a distance, as is the more general practice today, would have given greater depth doses and probably have given better results.

VULVA, Benign and Malignant Tumors of, Folsome, C. E. J. A. M. A. 114: 1499, 1940.

Metaplasia and malignant change in apparently innocuous vulvar tumors are inadequately emphasized. Papillomas, sebaceous cysts, pigmented moles, leiomyofibromas, vulvar breast tissue, and sweat gland adenomas are some of the benign vulvar tumors which may, at a later date in a woman's life, degenerate to vulvar malignancy.

Treatment and care of the patient presenting herself with a vulvar cancer are tending to become more rational in the light of present anatomicopathologic knowledge of vulvar cancers. Vulvar surgery combined with resection of superficial and deep inguinal lymph nodes, the so-called Basset technique, with modifications as outlined by Taussig, continues to be the best treatment for carcinoma of the vulva.

By stressing periodic pelvic examinations, cancer educational programs may materially assist in preventing cancer of the vulva. By paying attention to simple lesions and the benign tumors of the vulva, the physician may prevent carcinoma of the vulva.

COLLOIDAL GOLD, A Method of Preparation, Bartholomew, R. J., and Gent, N. L.
Australian J. Exper. Biol. & M. Sc. 18: 89, 1940.

A method is described for the preparation of colloidal gold sols for use in the Lange test by the reduction of gold chloride with sodium citrate.

A sol of correct sensitivity can be prepared (a) by using a suitable amount of citrate in the preparation, (b) by adding acid to an initially "hard" sol, (c) by adding alkali to an excessively sensitive sol, (d) by mixing suitable proportions of a "hard" sol and an excessively sensitive sol. Method (b) is preferred for routine use, and a technique for preparation by this method is described.

Not a single failure has been encountered in preparing citrate-reduced sols, and the sols have been found so uniform in behavior that it seems unnecessary to use a "paretic" fluid for standardization.

The method follows:

Into a liter flask put 675 ml. distilled water, close the flask with a ground-in reflux condenser, and bring the water to the boil over a fairly large flame. Remove the condenser and add 7 ml. of 1 per cent gold chloride solution followed by 17.5 ml. of 1 per cent sodium citrate solution. Replace the condenser and continue the boiling for fifteen minutes. Remove from the flame and allow to cool.

To one 50 ml. portion of the sol add nothing, and to three other 50 ml. portions add 0.05 ml., 0.10 ml., and 0.15 ml., respectively, of N/10 hydrochloric acid. Set up each mixture by the conventional technique against a known "paretic" cerebrospinal fluid and against a known "normal" fluid, then allow the mixtures to stand overnight. Select the mixture which gives the strongest reaction with the paretic fluid, yet does not give a reaction greater than 0 0 1 1 0 0 0 0 0 with the normal fluid, then add the corresponding quantity of acid to the main bulk of the sol, thoroughly agitating the mixture during the addition.

TYPHOID, Isolation of Paratyphoid, Dysentery and, From Feces and Urine, Ruys, A. G.
Brit. M. J., April 13, p. 606, 1940.

This comparative study indicates that in cases of typhoid fever it is advisable to use the media of Wilson and Blair and of L. Muller; in paratyphoid B, those of Muller and Ruys; and in the enteric form of the disease, those of Kauffman and Ruys. Endo's agar should not be neglected because it may give a positive result one day earlier than any of the other media.

In bacillary dysentery both Leifson's desoxycholate-citrate agar and Endo's agar should be used.

SULFAPYRIDINE, Evaluation of the Clinical Toxicity of Sulfanilamide and, Brown, W. H., Thornton, W. B., and Wilson, J. S. J. A. M. A. 114: 1606, 1940.

The vomiting caused by the administration of sulfapyridine appears to be of both local and central origin. Mucilage of tragacanth and nicotinic acid are of value in combating the vomiting and other mild toxic reactions.

Although methemoglobinemia contributes to cyanosis in a small number of cases, sulfhemoglobinemia has not been encountered.

The serious toxic manifestations have been found twice as frequently in the series treated by sulfapyridine as compared with the series on sulfanilamide.

Oliguria, hematuria, pain in the costovertebral angle, and anuria are serious and fairly common complications of intensive sulfapyridine therapy, particularly when the concentrations in the blood are high. These sequelae are related to the insolubility of acetylsulfapyridine, which precipitates in characteristic crystals in acid and alkaline urines. For this reason, the fluid intake should approximate 3,000 c.c. or more in twenty-four hours, and the urine volume in a like period should not be allowed to fall under 1,000 c.c.

Although leucopenia occurs more frequently in the sulfapyridine series and especially when the dosage is heavy, it is also encountered in both series and may occur when the doses are small or treatment is of short duration.

Acute hemolytic anemia with icterus was encountered only in the cases in which sulfanilamide was administered. Both series comprised instances of gradual and suddenly developing anemia.

Three cases of granulocytopenia were encountered in 100 cases in which sulfapyridine was given. All three occurred in cases in which treatment was maintained for longer than fifteen days at low blood concentrations.

Patients treated with intensive doses and in whom high blood concentrations of sulfapyridine were attained showed a very high incidence of serious toxic reactions.

Drug rashes and fevers are useful signs of toxicity, but serious toxic complications may occur without these warnings.

Sulfapyridine may remain in the liver in small quantities for as long as forty days after chemotherapy has been terminated. No conclusion has been reached as to whether sulfapyridine causes hepatitis.

Sulfapyridine is essentially more toxic than sulfanilamide.

GLUCOSE TOLERANCE, Reverse or "Paradoxical" Blood Sugar Response to Ingested Glucose, Wheelon, H. *Endocrinology* 26: 743, 1940.

Laboratory and clinical findings are presented on 40 patients, each of whom showed a reverse or "paradoxical" blood sugar response to the ingestion of glucose, and a sugar-free urine.

The average fasting blood sugar level for this series was 140 mg., or a figure indicative of mild hyperglycemia. Blood sugar levels of 70 mg. or less were found twenty times on 10 patients during the glucose tolerance test. The initial blood sugar response of 14 glucose tolerance tests performed on 7 patients subsequent to the initial tests was an average elevation of 33 mg. above the fasting level, followed by a maximum depression of 19 mg. below the fasting reading. Five patients in the series of 7 initial tests developed hypoglycemic sugar levels ten times. A like number of patients developed hypoglycemic levels eight times in the fourteen subsequent series of tests. Two patients only, however, developed hypoglycemic levels in each of the two series.

Ninety-nine physical, and 248 chemical, a total of 347 determinations were made on the 40 patients in addition to those incident to the glucose tolerance test, urine and Wassermann examinations. A total of 39, or 40 per cent, of the 99 physical determinations lay beyond the limits of normal variation. A total of 107, or 43 per cent, of 248 chemical determinations lay outside the range of figures assumed to represent "normal variations."

Seventy-two clinical diagnoses, aside from those established by laboratory procedures, were made on the 40 patients. Diagnoses referable to disturbances of the nervous system were made on 29, or 73 per cent, of the 40 patients.

A correlation of the various findings shows that each of the 40 individuals studied had an average of 5.5 deviations from normal standards, in addition to the primary one, or reverse response to the ingestion of glucose.

It may be concluded that a rather large number of physical and chemical abnormal variations and diagnosable clinical states are found associated in various degrees with

reverse or "paradoxical" blood sugar responses to the ingestion of glucose. It may be concluded also that the medical management of patients showing reverse glucose responses, as demonstrated on 7 patients, results in the amelioration of the symptomatology and a return of the glucose response toward the usual normal.

SODIUM SULFAPYRIDINE, Use of, by Hypodermoclysis, Taplin, G. V., Jacox, R. F., and Howland, J. W. J. A. M. A. 114: 1733, 1940.

Sodium sulfapyridine has been used by hypodermoclysis in more than 50 cases of pneumonia and numerous other conditions for which sulfapyridine was indicated but in which oral administration was difficult or impossible. The drug was given in from 0.3 to 0.7 per cent solution in physiologic solution of sodium chloride and no local reactions were observed in any of the cases. More than 1,100 Gm. of the drug have been given by this method.

This route of administration is advocated when the drug is not tolerated by mouth or is poorly absorbed from the gastrointestinal tract and when a high sustained concentration in the blood is imperative.

SULFANILAMIDE, Absorption of, as an Index of Blood Flow in the Intestine of Man, Stead, E. A., and Kunkel, P. Am. J. M. Sc. 199: 681, 1940.

The blood flow in the human intestine has been investigated by determining the appearance time and the concentration curve in the blood of free sulfanilamide when a known amount of sulfanilamide in solution is introduced directly into the small intestine or colon.

Under basal conditions a blood level of 6 to 8 mg. per 100 c.c. of free sulfanilamide was obtained in ten to thirteen minutes when 300 c.c. of a 1 per cent solution of sulfanilamide were placed in the duodenum.

Heating the body or inducing collapse in an individual with postural hypotension did not alter the curve of sulfanilamide in the blood. This is interpreted as indicating that the basal blood flow to the small intestine was low and that the rapid appearance of sulfanilamide in the blood was the result of its rapid diffusion.

Under basal conditions sulfanilamide was absorbed much more slowly from the large bowel. When 300 c.c. of a 1 per cent solution of sulfanilamide were given rectally, the blood level rose to between 2.4 and 4 mg. per 100 c.c. at the end of one and one-half hours.

Pitressin failed to influence the rate of absorption of sulfanilamide when the substance was given by duodenal tube. Pitressin caused a delay in absorption when the sulfanilamide was placed in the large bowel.

The rapid absorption of the sulfanilamide in the collapse induced by the upright position in a person with postural hypotension suggested that even in shock sulfanilamide diffuses so rapidly that it is adequately absorbed once it is present in solution in the small intestine. Dilatation of the stomach and closure of the pylorus may, however, prevent the drug from reaching the small intestine.

SULFATHIAZOLE, Crystalline Concretions in the Renal Tubules Following, Pepper, D. S., and Horack, H. M. Am. J. M. Sc. 199: 674, 1940.

Concretions obstructing the renal tubules and in the pelvis and bladder were discovered at autopsy in a patient following treatment with sulfathiazole. On analysis the material was composed of a derivative of sulfathiazole. The gross and histologic findings in the kidneys were identical with those described by others as occurring in experimental animals. The probable etiologic factors influencing the site of the precipitation of sulfapyridine and sulfathiazole crystals are discussed. Because of the intrarenal precipitation of sulfathiazole, it is felt renal complications resulting from the use of this drug may be more serious than those following the use of sulfapyridine.

REVIEWS

Books and Monographs for Review should be sent direct to the Editor,
Dr. Warren T. Vaughan, Professional Building, Richmond, Va.

Electrocardiography*

THIS book is intended to serve as an introduction to the study of electrocardiography and is designed for the use of the general practitioner, the medical student, and others who are not primarily cardiologists. The use throughout the book of the standard nomenclature advocated by the American Heart Association is to be commended.

The book is an atlas of one hundred electrocardiographs with clinical diagnosis and interpretations. There is an interlarding of textual material. Although the authors state that the tracings have been carefully standardized, the reviewer would have preferred to have the standardizations given with each tracing, instead of being confined to the first. It is felt, however, that the aim of the authors is achieved very satisfactorily, and that the book may be recommended to the audience for which it was intended.

Vitamin E†

IN APRIL, 1939, a symposium was held on vitamin E in London. Taking part in this international, but predominantly British, discussion were many leaders in the field. The proceedings were edited by A. L. Bacharach and J. C. Drummond. The monograph constitutes a valuable summary of our knowledge in a highly important biochemical field.

The little book falls naturally into three subdivisions: the chemical structure and properties of tocopherol (vitamin E); the physiologic action of vitamin E and the consequences of vitamin E deficiency; and the clinical and veterinary uses of wheat germ oil and vitamin E preparations. In the eighteen years since the discovery of an antisterility vitamin its structural formula has been established and it has been synthesized. In addition to the biological estimation, there are four chemical methods for its analysis. The therapy of avitaminosis E is fast becoming rationalized. Although much work remains to be done before the last word has been said on vitamin E, this book brings together in a concise form the great deal that has already been accomplished.

CORRESPONDENCE

Wichita, Kansas,
October 9, 1940.

The Editor,
JOURNAL OF LABORATORY AND CLINICAL MEDICINE.
Dear Sir:

Perhaps some of the readers are tired of being unable to think while shaking a Kahn rack full of test tubes in their Kahn shaking machine. Perhaps, at the same time, they do not wish to throw away their Kahn racks and purchase the new rubber coated ones, which are silent in operation. Here is a way to silence the old racks.

A bottle of "Rug Sta," which is manufactured by the makers of Old English Wax, will do the trick. Merely take an old tooth brush and lay the "Rug Sta" on in a thick smooth coat. It is white when wet and colorless when dry. Two coats will usually suffice to make a silent test tube rack out of the noisiest of them.

PROGRESS

PHYTOTOXIC REACTIONS OF SOME BLOOD SERA*

WITH BIOMETRIC ANALYSES

DAVID I. MACHT, M.D., F.A.C.P., AND MOSES B. MACHT, A.B.†
BALTIMORE, MD.

INTRODUCTION

NEARLY twenty years ago, while studying the general laws underlying physiologic and pharmacologic reactions, one of us (D. I. M.) conceived the idea of making comparative studies of the effect of various drugs and chemicals on living plant protoplasm in contrast to living animal test objects. By pharmacology, as it is taught in most of our medical and research institutions, is meant the investigation of the effects of drugs and poisons on living animals. Strictly speaking, it is *zoopharmacology*. However, just as the domain of physiology is subdivided into *zoophysiology*, i.e., study of physiologic functions of animals, and *phytophysiology*, or plant physiology, or study of physiologic functions of plants, so can the science of pharmacology be subdivided into *zoopharmacology* and *plant pharmacology*, or study of the effects of drugs and poisons on living plants. Initial studies of this type, carried out by one of us (D. I. M.), led to such interesting findings that as a result there was developed a new department of science, to which was given the name of "*phytopharmacology*." A number of the discoveries made in the evolution of this branch of pharmacology have a direct bearing on clinical medicine and in the present paper we shall describe and explain some of these developments.

The effects of drugs and poisons on plant tissues may be studied in various ways. Thus the plant physiologist entering this field may study the effects of chemicals on germination of seeds, on growth of roots and stems, on flowering

*From the Pharmacological Research Laboratory, Hynson, Westcott, and Dunning, Inc., Baltimore.

†Candidate for Ph.D. in Psychology, Johns Hopkins University.

and flowers; the effects of various chemicals on geotropic and heliotropic properties of plants, on processes of respiration and transpiration, on growth of yeasts and fungi, on behavior of chloroblasts, on protoplasmic streaming, photosynthesis, oxidation and reduction phenomena, etc. For practical pharmacologic purposes it was found that quantitative phytopharmacologic studies could be most conveniently made by measuring the growth of roots and sometimes of stems of certain seedlings reared in artificial plant physiologic nutrient media. Growth of such seedlings in different plant physiologic solutions containing a definite proportion of the salts necessary for normal growth and of other seedlings of the same type reared in similar solutions to which small amounts of unknown drugs had been added, could then be quantitatively compared. For such studies various plant physiologists have found the seeds of the *Lupinus albus* very useful, and we and our collaborators have employed them extensively in our phytopharmacologic researches.

STUDIES ON COCAINE

The earliest phytopharmacologic studies, carried out by Macht and Livingston,^{2, 3} dealt with the pharmacodynamic effects of the alkaloid cocaine and its products of hydrolysis on growth of *Lupinus albus* seedlings under standard ecologic conditions. It is well known that the cocaine molecule can be easily split by hydrolysis into three components, one a complicated nitrogenous base known as ecgonin, another, a molecule of a simple aromatic benzoic acid, and the third, a molecule of methyl alcohol; and that cocaine itself, or in the form of its simple salts, is a powerful poison for animals and animal tissues. Ecgonin is not as toxic for animals as cocaine itself; small doses of methyl alcohol are certainly not toxic for most lower animals; and benzoic acid as such, or in the form of its sodium salt, is practically nonpoisonous. A study of cocaine and its products on living seedlings of *Lupinus albus* by methods described elsewhere and to be discussed at length in the present paper, revealed that cocaine itself is not extremely poisonous for plant test objects. On the other hand, sodium benzoate, which is practically nonpoisonous for animal tissues, was very toxic for living plant protoplasm. A 2 per cent concentration of cocaine hydrochloride in the plant physiologic solutions was required to inhibit growth of *Lupinus albus* seedlings completely, while a 0.007 per cent solution of sodium benzoate accomplished the same result. It thus became apparent that while cocaine was much more poisonous for living animal tissue than for plant protoplasm, one of its components, sodium benzoate, was far more toxic for plant tissue than for living animals. This curious observation suggested that the presence of some toxic substances, in quantities not pronounced enough to affect animals, might be detected by means of living plants. Accordingly, one of us (D. I. M.) debated the feasibility of employing plants to determine the toxicity of certain bloods which could not be demonstrated by any other biological or physicochemical method. Such inquiry has been attended by more success than was ever anticipated.

STUDIES ON MENOTOXIN

The first phytopharmacologic studies undertaken on blood toxins were suggested by certain historical considerations. The belief is popular among all

races, ancient, medieval, and modern, that a woman at time of her menstruation is "unclean," using the word in a transitive sense as contaminating. Such a person was supposed to defile everything with which she came in contact. Thus, for instance, flowers touched by a menstruating woman withered; fruit that she canned became spoiled; dough that she kneaded failed to rise; and wine that she expressed from grapes soured. No careful investigation was made of the subject until 1920, when Professor Shiek observed that beautiful, freshly cut flowers handled by a menstruating woman assistant commenced to fade soon after she had touched them. Reporting this circumstance and the similar results he had obtained in experiments with flowers in the hands of other menstruating women, Dr. Shiek expressed the hope that some one would undertake to study the subject in a thoroughly scientific quantitative manner. Such a scientific investigation was carried on by Macht and Lubin,⁴ who demonstrated quantitatively that small amounts of menstrual blood sera, as compared with normal sera of the same individuals, inhibited the growth of *Lupinus albus* seedlings. Moreover, the presence of this toxic substance, named "menotoxin" (by D. I. M.), was demonstrated by similar phytopharmacologic methods in the saliva, milk, urine, tears, and particularly the sweat, of menstruating women. These studies, published seventeen years ago, were later supplemented by those of Macht and Davis,⁵ who showed that chemically menotoxin is probably akin to oxycholesterin. Their findings, which other investigators confirmed by different means, are now of special interest in connection with phytopharmacologic studies on the nature of the sex hormones, also found to be closely related in chemical structure to cholesterol. Most important of all, however, the first studies on menotoxin, instigated by the interest in medical history (D. I. M.), led to discovery of toxic reactions in the blood of patients suffering from various pathologic conditions. In the present paper we purpose to recapitulate the results already obtained in studies made on various types of blood sera and to describe the research we are now conducting and the phytotoxic reactions we discovered in bloods from other diseases.

TOXIC SERA

The phytopharmacologic method will be described in detail in the second part of this paper. Briefly, it consists of studying the root growth of *Lupinus albus* seedlings in normal plant physiologic solutions and comparing it with that of similar seedlings in the same kind of solution, to which had been added definite concentrations of the blood sera or plasma to be examined. The average root growth of *Lupinus albus* seedlings in twenty-four hours under standard conditions of temperature and light in a solution containing an unknown serum or chemical divided by the average increment of control roots is known as the phytotoxic index or index of growth, which may be expressed by the formula,

$$\text{Index} = \frac{X}{N}.$$

The average phytotoxic index of root growth of *Lupinus albus* seedlings in plant physiologic solutions containing small amounts of blood sera from hundreds of

normal individuals was found to be 70 to 75 per cent. Blood sera obtained from a number of women at onset of catamenia yielded an average phytotoxie index of 51 per cent. One of the most remarkable findings made in early phytopharmacologic studies was that obtained during investigation of sera from persons with various anemias. Blood sera of patients with pernicious anemia, male and female, definitely inhibited growth of *Lupinus albus* seedlings.^{6, 7} Specimens from the first 50 patients examined yielded an average index of 44 per cent, a reading considerably lower than that given by menstrual blood. Such a phytotoxie effect was exerted not only by the blood but also by the spinal fluid⁸ and stomach washings⁹ from persons with pernicious anemia. Sera of certain other diseases, listed in Table I, also exhibited a characteristic phytotoxicity.

TABLE I
TOXIC SERA

KIND OF BLOOD SERUM	AVERAGE NUMBER OF CASES	PHYTOTOXIC INDEX (%)
Normal human	500	75
Menstrual	50	51
Pernicious anemia	50	44
Aplastic anemia	10	56
Pemphigus	200	59
Leprosy	22	47
Trachoma	100	48
Hodgkin's disease	10	60

TABLE II
OTHER ANEMIAS

KIND OF BLOOD SERUM	PHYTOTOXIC INDEX (%)
Severe secondary anemia	65 to 69
Carcinoma	70
Pellagra	70
Hemolytic jaundice	74
Obstructive jaundice	71
Malaria	70
Mononucleosis	80
Banti's disease	75
Lymphatic leucemia	68
Myelogenous leucemia	78
Sprue	60

Sera from patients with aplastic anemia gave an index of 50 per cent; those obtained from persons with leprosy, a reading of 47 per cent; from trachoma, 48 per cent; from Hodgkin's disease, 60 per cent. Most important of all, blood sera from the baffling skin disease, pemphigus, yielded an average phytotoxie index of 59 per cent. These phytotoxie reactions assume a profound significance when considered with the findings obtained in studies of sera from other forms of anemia and dermatoses.^{10, 11} Table II exhibits the findings obtained with sera from secondary anemias, from the anemias of malignant disease, from various types of leucemia and certain other pathologic conditions. Thus was

established the availability of a test for differentiating between pernicious anemia and other types of anemia, between pemphigus and other forms of skin disease simulating it, and between trachoma, regarded by many as a systemic disease, and other varieties of conjunctivitis and localized eye disease.¹²

TABLE III
NONTOTOXIC SERA

KIND OF BLOOD SERUM	PHYTOTOXIC INDEX (%)
Syphilis	81
Tuberculosis	78
Scarlet fever	79
Measles	80
German measles	80
Varicella	80
Eclampsia	75
Postpuerperal (12 weeks)	80

Of equal interest were the *negative* findings derived from phytopharmacologic study of sera from certain grave pathologic conditions, i.e., syphilis, tuberculosis, scarlet fever, and other exanthemas, and also eclampsia. The phytotoxic indices of some of these nontoxic sera are shown in Table III. Tables I to III are obviously of clinical interest and throw some light on the etiology of certain diseases, such as pemphigus, pernicious anemia, trachoma and eclampsia. The phytopharmacologic test is also helpful in differentiating some pathologic conditions having certain points of resemblance. Thus, for instance, one of us by this method has differentiated between syphilis, tuberculosis, and leprosy. Further data on the subject may be found elsewhere. In this connection it is interesting to note that the average phytotoxic index of normal human blood specimens, 70 to 75 per cent, is practically the same as that obtained with sera of other mammalia, small and large, and of most fish and other cold-blooded animals with the exception of reptiles.

TABLE IV
SERA FROM VIRUS DISEASES

KIND OF BLOOD SERUM	ANIMAL INOCULATED	PHYTOTOXIC INDEX OF CONTROL (%)	PHYTOTOXIC INDEX OF VIRUS SERUM (%)
Fowl pox	Chicken	71	80
Vaccinia	Rabbit	73	80
Vaccinia	Rat	67	78
Herpes simplex	Rabbit	72	84
Virus fixé	Rabbit	75	61
Virus fixé	Guinea pig	81	65
Virus III	Rabbit	72	84
X-virus	Cat	70	65
Rous' tumor	Chicken	66	92
Shope's fibroma	Rabbit	77	96
Infectious myxomatosis	Rabbit	75	85
Rivers' lymphocytic choriomeningitis	Guinea pig	79	102
Poliovirus	Monkey	61	62
Tetanus toxin alone, 86 per cent	Rabbit	75	63
Strychnine nitrate, 93 per cent	Rabbit	77	61

ATOXIC SERA

The negative results obtained with sera of certain diseases listed in Table III suggested an investigation which was conducted by Macht and Gardner,¹² who studied blood specimens from various animals experimentally inoculated with a number of virus diseases.

Blood was taken from such animals before experiments were begun and later after the virus diseases were fully developed. It was found that sera from animals inoculated with the virus diseases yielded phytotoxic indices much higher than normal blood specimens from the same animals. Bloods from animals inoculated with virus fixé or virus hydrophobia were the only exception, and the increased toxicity of such specimens was shown to be due to convulsions produced by the virus because similar findings were made after injection of small amounts of strychnine and tetanus toxin (see Table IV).

BLOOD SERA FROM PEMPHIGUS, X-RAYED, AND PSYCHOTIC PATIENTS

During the past five years the phytopharmacologic test has been a routine procedure in various researches made in these laboratories. Such investigation has been made on the comparative toxicity of various synthetic inorganic and organic compounds, the growth hormones, the influence of vitamins on plant growth, the pharmacologic effects of sex hormones on growth of plants, and a search for toxins in various diseases of the blood. Special studies, described here in detail, were made on (1) blood sera from animals and human beings after their exposure to x-rays, (2) the toxicity of pemphigus blood sera, and (3) blood sera from patients with various organic and functional psychoses.

The first problem undertaken concerned the effects of prolonged administration of x-rays and had a direct bearing on the so-called roentgen sickness. Repeated experimentation revealed that from twenty-four to forty-eight hours after exposure of various animals to therapeutic doses of x-rays, a toxic substance was developed in their blood which could be demonstrated phytopharmacologically.¹⁴ As compared with normal specimens that had been drawn from the same animals before treatment with x-rays, blood sera obtained afterward were quite toxic, but the toxicity varied with the region of the body irradiated. When these tests on normal animals had been completed, a similar series was begun with human beings, from whom blood sera were obtained both before and after their treatment with x-rays for malignant and nonmalignant pathologic conditions. It was found that specimens from patients who had been subjected to such exposure definitely inhibited growth of *Lupinus albus* seedlings. Further investigation revealed the fact that not only sera from patients treated with x-rays but also those from apparently healthy physicians, technicians, and attendants in roentgenologic clinics were definitely toxic for *Lupinus albus*, as compared with control specimens from unexposed normal individuals. A number of these findings have been published, but the subject itself, which is of great clinical importance, is still under investigation. Table V shows the striking data already obtained.

TABLE V
EFFECT OF X-RAYS ON BLOOD OF CLINICAL PATIENTS

CASE NO.	DIAGNOSIS	PHYTOTOXIC INDEX		TIME ELAPSING BETWEEN X-RAY TREATMENT AND TAKING OF SPECIMEN	DOSAGE EMPLOYED (r.)

We still conduct another phytopharmacologic study of pathologic blood sera, initiated a year ago by Dr. Max Hayman, then a resident physician at Springfield State Hospital, Sykesville, Md., and one of us (D. I. M.). This research consists of a systematic examination of blood sera from various types of functional and organic psychoses. A complete presentation of the findings will be published in due time after the blood sera from a larger number of cases have been studied. Such an investigation is in progress. Table VI shows the results obtained after repeated examination of sera from eight psychotic patients. The case of one such patient will be described in detail here.

TABLE VI
PHYTOTOXIC INDICES OF SOME PSYCHOTIC BLOOD SERA

PATIENT	DIAGNOSIS	PHYTOTOXIC INDEX (%)
E.S.	Schizophrenia, catatonic hypokinetic type	44
H.R.	Schizophrenia, catatonic hypokinetic type	42
F.N.	Schizophrenia, catatonic hyperkinetic type	58
D.H.	Schizophrenia, catatonic hyperkinetic type	58
C.H.	Involuntional melancholia type	52
M.R.	Involuntional melancholia type	50
B.B.	Manic-depressive type	54
J.H.	Manic-depressive type	57

By far the most extensive phytopharmacologic study, which is still in progress, has been that made by the dermatologist, Dr. Isaac R. Pels, and one of us (D. I. M.) on pemphigus blood sera, which exhibited more toxicity than specimens obtained from all other skin affections, with the exception of leprosy. In fact, the phytopharmacologic test has become not only a valuable aid in diagnosing and differentiating this strange malady from dermatitis

herpetiformis and other dermatoses, but also an important contribution to the etiology of pemphigus. It has been most useful in establishing a diagnosis in the early stages of pemphigus. Although pemphigus is a rare disease, Machl and Pels up to the present time have examined phytopharmacologically more than 2,600 specimens taken from various skin diseases and forwarded to them for differential diagnosis by physicians in the United States and Canada. Routine phytopharmacologic examination of these blood sera has resulted in a positive diagnosis of pemphigus in fully 90 per cent of the cases, a diagnosis which was confirmed by clinical findings as the disease progressed. This figure in itself is incontrovertible proof of the value and reliability of the phytopharmacologic test for this disease. Because of the growing importance and practical value of the phytotoxic reaction in routine examination of blood sera from various diseases, and because of the difficulties some clinicians experience in carrying out the test, we purpose to describe it in considerable detail and to evaluate its reliability in the light of the latest biological and biometric information available.

METHOD OF EXPERIMENTATION

The method of detecting toxic reactions in blood sera of pernicious anemia, pemphigus, and other pathologic conditions consists of determining quantitatively the increment in length of the single, well-defined, straight roots of seedlings of *Lupinus albus*, after their growth for twenty-four hours in a plant physiologic (Shive) solution containing a small amount of the blood serum to be tested. The average root length of ten or more such seedlings is measured, and the plants are immersed in a suitable plant physiologic nutrient solution containing all the salts or electrolytes necessary for perfect growth. Seedlings are grown in such solutions for twenty-four hours under standard conditions of light and temperature, after which the average increment in root length is determined. These seedlings grown in Shive solution are compared with similar seedlings placed for the same number of hours in the same kind of plant physiologic solution containing, in addition, a definite quantity of an unknown chemical, blood serum, or other substance to be tested. When a pathologic specimen of blood is examined, the growth of seedlings is determined not only for one group in plant physiologic solution alone, but also for another in Shive solution containing a small percentage of normal blood serum. It is customary in all phytopharmacologic work to employ 1 per cent solutions of blood sera.

To make a correct phytopharmacologic test a great deal of training is required not only in ordinary pharmacologic methods, but also in laboratory technique pertaining to plant physiology. Beginners who anticipate success with the first attempt at such experimentation will probably be disappointed. Without previous practice even experienced laboratory workers have occasionally been unable to germinate the seeds, much less to raise the seedlings and measure them in phytopharmacologic tests. In this highly specialized work, as in any other complicated laboratory technique, negative results in the hands of a tyro count for little or nothing.

In examining specimens for pemphigus toxin, fresh blood serum is almost invariably employed in making the test although, as Macht and Grumbein have pointed out,¹⁵ dried specimens of whole pemphigus blood or of blood serum retain much of the toxin and may be used for phytopharmacologic examination when necessary. Occasionally, serum from bullae is also tested for the pemphigus toxin. A 1 per cent solution is prepared by dissolving the serum in equal parts of distilled water and Shive plant physiologic solution,¹⁶ which consists of 10.4 c.c. of a 0.5 molar solution of chemically pure calcium nitrate, 30 c.c. of a 0.5 molar solution of chemically pure magnesium sulfate, and 36 c.c. of a 0.5 molar solution of diacid potassium phosphate (KH_2PO_4), to which is added enough distilled water to make one liter. In testing body fluids for clinical purposes, it is absolutely necessary to use salts of the highest chemical purity. Even the test tubes employed in such work should be of a special type, i.e., they should be made of hard or nonalkaline glass, in order that all conditions of experimentation may be rigidly controlled and standardized. The hydrogen-ion concentration of a mixture of equal parts of distilled water and Shive solution is usually about 5.4. When blood serum is added to make a 1 per cent solution, the pH shifts toward the alkaline side and varies from 5.4 to 5.6. Previous publications have shown that such slight variations in pH have little effect on the growth of seedlings immersed in the solutions and are certainly not sufficient to account for differences in toxicity between specimens of serum from both normal and diseased persons. As a matter of fact, there is usually no difference at all in hydrogen-ion concentration between a 1 per cent solution of serum from a normal individual and a similar solution from a diseased one.

In making the phytopharmacologic test, we employed a special apparatus containing twenty-three parallel rows of ten perforations for holding test tubes in an upright position. The ten tubes in the first row, and sometimes those in two or three such rows, are filled with control solutions consisting of equal parts of Shive saline solution and distilled water. Succeeding rows of ten tubes each are filled with 1 per cent solutions of various specimens of blood serum to be dissolved and tested in the plant physiologic saline solution. The *Lupinus albus* seedlings are then carefully selected, measured, and immersed in the solutions filling the upright tubes. For ordinary routine examinations an average of ten seedlings for each solution to be tested is usually sufficient for a single experiment. The test should be repeated on several consecutive days, however, until the phytotoxic indices differ from each other by not more than 5 per cent. Such repetition of the test, on two days at least, is necessary because occasional crops of *Lupinus albus* yield seedlings impervious to saline solutions of toxins. Such seedlings give a negative reading or an index considerably higher than that yielded by controls in normal blood serum. While it is true that specimens of serum obtained from patients with certain rare conditions (i.e., virus diseases, etc.) consistently give higher readings, such conclusions can be deduced only from several tests. In dealing with specimens of serum of patients suspected of having pemphigus, pernicious anemia, or some similar condition, negative or exceedingly high readings after a single examination should be regarded as "no takes" if in several repetitions of the test toxic effects are definitely exhibited.

The seeds employed for the phytopharmacologic test by the Macht-Livingston school of plant physiologists are those of *Lupinus albus*, large variety. The dry seeds, approximately 10 mm. in diameter, are obtained from Italy, where this variety of *Lupinus albus* is widely cultivated. The test can be made with the small varieties of *Lupinus albus*, approximately 6 mm. in diameter, which are grown in this country, but the percentage of germination and uniformity of size of these seeds are much less than those of the French or Italian varieties. Seeds of the giant *Lupinus albus*, 13 to 15 mm. in diameter, may also be employed in this work and have the advantage of possessing a very definite line of demarcation between stem and root. However, Macht and his associates have derived the best results from the large Italian variety of *Lupinus albus* seeds, which are remarkably hardy and will germinate even when five years old, although the most satisfactory results are obtained with seeds that are one to two years old. *Lupinus albus* seeds are soaked overnight in tap water. The next day the swollen seeds are ready for planting. Finely ground sphagnum was found to be the most suitable medium for the problem in hand. The sphagnum should not only be ground to a fine powder but should also be impregnated with just the amount of water most suitable for optimum germination. Here the beginner in phytopharmacology encounters his first difficulty. If the moss contains too much moisture, the seeds will rot, fungi will develop, germination will be defective, and the seedlings will be diseased. If it contains too little water, the seedlings will suffer from malnutrition and lack of turgor and will exhibit a stunted growth. A great deal of experimentation has proved that the best results are obtained with sphagnum containing from 70 to 80 per cent of water by weight. Such a medium can be successfully prepared only after considerable practice. Sphagnum prepared for the germination of seedlings must be rinsed several times with hot water to free it from an excess of acid matter, which would interfere with proper development of the plants. It must also be well aerated before it is deposited in the glass jars in which the seeds are to be planted. Swollen seeds, which have been soaked overnight, are planted closely together with the hili pointing down. In this way a large number of seedlings can be raised in a comparatively small area. A light layer of the moss is then sifted over the seeds, and the covered jar is allowed to stand in the dark for several days at room temperature. When the weather is mild, the seedlings are generally of convenient length for testing on the third day after planting. In winter, however, germination progresses more slowly even at room temperature, and the seedlings are not long enough until the fourth day after planting.

The most suitable seedlings for the phytopharmacologic test are those with roots measuring from 35 to 60 mm. Shorter seedlings may be employed, but their growth is not usually so rapid as that of the longer ones. For this reason, in recent years we have been discarding those less than 30 mm. long. On the other hand, much longer seedlings exhibit curvatures which make them difficult to measure. Healthy seedlings are taken out of the moss; the adhering particles are removed by gentle brushing or rinsing, and the length of their

roots is measured with a millimeter rule. Here the beginner encounters a second difficulty. While the line of demarcation between root and stem is usually definite and easy to find with the naked eye, with or without the aid of some innocuous staining solution, consistently accurate readings can be made only after much practice and experience. After the seedling has been measured, it is immersed in a tube of either the control solution or the blood serum solution to be examined. In this way ten seedlings are selected for each solution tested, including controls. The roots of the seedlings in any given experiment must be measured both at the beginning and at the end of the test by the same person. A woman experimenter should not handle the plants at the time of catamenia. All experimenters should wash their hands carefully before touching the objects to be tested.

An important detail of technique is the *matching* of seedlings, i.e., the selection of seedlings of as nearly the same length as possible. Experiments with living plants are generally more reliable than those with living animals because of the vastly larger number of the former available and the physical and economic obstacles to such wholesale experimentation with higher animals. To insure maximum accuracy in performing the phytopharmacologic test, however, the seedlings selected should be of as nearly the same length as possible. Especially should the individual plants in corresponding positions in different rows be closely matched. This is accomplished by filling the first tube of each row with seedlings of as nearly the same length as possible, and then filling the second tube in each row with similarly matched seedlings and matching in the same way all the plants in corresponding tubes in the remainder of the rows.

When such a procedure is followed, deviations in readings due to differences in growth between seedlings which are either too long or too short at the outset of the experiment are reduced to a minimum, and a more reliable comparison can be made with regard to the effect of various solutions on the growth of the roots.

After all the seedlings have been measured and allotted to their respective tubes, the outfit containing them is placed in a refrigerator or a low-temperature incubator. The seedlings are allowed to grow there in the dark for twenty-four hours, at the end of which time they are measured again, and the average increment of growth in control and unknown solutions is determined. The average growth of roots in any given solution of blood sera divided by the average increment in the length of roots of control seedlings grown in Shive solution alone and maintained under exactly the same light and temperature, gives the so-called phytotoxic index of growth for that serum. Thus blood from normal persons yields a phytotoxic index ranging from 70 to 75 per cent, and serum from patients with pemphigus, a reading of 58 or 59 per cent.

Perhaps the most important single factor affecting phytopharmacologic testing of serum from patients with pemphigus is the temperature. It is absolutely

necessary that seedlings grown in various solutions of serum be maintained at the temperature most suitable for the test. In earlier publications one of us (D. I. M.) specified 20° C. as the temperature most suitable for such work. Later experience, however, has shown that the best results in testing specimens of serum from patients with pemphigus are obtained with seedlings grown at a considerably lower temperature. The blood from such patients changes rapidly when kept at room temperature. The pemphigus toxin decomposes even at from 18° to 20° C. in the presence of the slightly acid Shive solution. Furthermore, the stimulus to growth of seedlings kept at temperatures higher than 15° C. or 60° F. is so great that slight inhibitions produced by the presence of small quantities of toxin are masked. On the other hand, when the seedlings are maintained at temperatures below 15° C., the growth of all, even those in normal control solutions, is greatly retarded; as a consequence, the phytotoxic indices yielded by specimens of both toxic and normal blood are much lower than they should be. In other words, seedlings grown in solutions at temperatures lower than 15° C. give more toxic readings than those grown in similar solutions at 15° C. Of all the ecologic factors playing roles in phytopharmacologic work with blood, temperature is the most important. Undoubtedly some investigators attempting the test have obtained discordant results because they did not regard this all-important ecologic factor. It is obvious, moreover, that all specimens of blood sent for phytopharmacologic testing, especially those from patients in whom pemphigus is suspected, should be protected from light, and, preferably, kept on ice. One of us (D. I. M.) has repeatedly observed that the red corpuscles of blood affected by pemphigus undergo decomposition much more rapidly than normal erythrocytes and effect a purple hemolyzed fluid quite unsuitable for phytopharmacologic examination.

For investigative purposes in connection with new problems involving determination of small differences in growth of seedlings placed in control and unknown solutions, respectively, the phytopharmacologic test can be made more accurate by "proving" the seeds and seedlings. In such cases, after seeds have been soaked and germinated in sphagnum, and the root growth of a large number has been measured, they are placed in solutions containing equal parts of distilled water and Shive. The growth of all these seedlings and their roots under standard conditions, i.e., in the dark and at a temperature of 60° F., is then determined, and only those are selected for further phytopharmacologic work which show approximately the same rate of growth, a procedure which eliminates plants weaker than others and renders the readings much more reliable. It is unnecessary to reiterate that the findings obtained by the writers with large numbers of proved seedlings are at least as reliable as those derived from any zoopharmacologic test. By use of the phytopharmacologic method it is possible to determine the toxicity of many unknown substances with various controls for hundreds of biological test objects grown simultaneously, a feat very difficult to accomplish in zoopharmacologic experimentation and possible then only at the cost of much more time, money, and labor in a highly subsidized laboratory.

STANDARD DEVIATION, PROBABLE ERRORS, AND CRITICAL RATIOS

Illustrative Experiments

To illustrate the reliability and utility of the phytopharmacologic test of various pathologic blood sera, five sets of experiments are detailed and analyzed by modern statistical methods.^{17, 18} All five were carried on simultaneously under exactly the same conditions, and in each series there were 50 *Lupinus albus* seedlings with roots from 35 to 50 mm. in length. In the various solutions these seedlings were grown in the dark at 60° F. for twenty-four hours, at the end of which period the roots were measured again, and the phytotoxic indices were calculated. In Experiment A 50 control seedlings were grown in a mixture of equal parts of Shive and distilled water. Into the Shive solution, in which all the other series of seedlings were also grown, was introduced 1 per cent of (1) a normal human blood serum in Experiment B, of (2) a random specimen of blood from a patient tentatively diagnosed clinically as pemphigus in Experiment C, of (3) a serum obtained from a person after exposure to x-rays for nonmalignant disease in Experiment D, and of (4) a serum from a patient afflicted with schizophrenia of the hypokinetic type in Experiment E.

EXPERIMENT A

Increment in Root Length of 50 Controls in Shive Solution and Distilled Water (1:1)

17	16	14	12	13	13	13	18	12	14
23	15	13	15	16	9	13	14	13	14

7	7	4	7	9	4	2	4	5	5

Average increment = 6.0 mm.

Phytotoxic index of x-ray blood serum = 46 per cent.

$$\sigma = \sqrt{\frac{\sum D^2}{N}} = 0.2$$

$$P. E. = \frac{0.6745 \times \sigma}{\sqrt{N}} = 0.019$$

$$P. E. \text{ diff.} = \sqrt{\frac{\overline{PE^2}}{\text{Normal serum}} + \frac{\overline{PE^2}}{\text{X-ray serum}}} = 0.17$$

Correlation of Normal Serum and X-ray Serum Readings:

$$\text{Validity or critical ratio} = \frac{D}{P. E. \text{ diff.}} = 23$$

EXPERIMENT E

Increment in Root Length of 50 Seedlings in 1 Per Cent Blood Serum. Obtained From a Psychotic Patient

9	6	7	2	7	4	9	8	8	5
6	3	7	5	5	5	2	7	9	5
6	7	6	3	6	2	9	3	7	5
6	7	6	7	7	9	6	5	5	4
6	6	9	4	7	5	8	5	7	6

Average increment = 6.0 mm.

Phytotoxic index of psychotic serum = 46 per cent.

$$\sigma = \sqrt{\frac{\sum D^2}{N}} = 0.183$$

$$P. E. = \frac{0.6745 \times \sigma}{\sqrt{N}} = 0.017$$

$$P. E. \text{ diff.} = \sqrt{\frac{PE^2}{\text{Normal serum}} + \frac{PE^2}{\text{Psychotic serum}}} = 0.17$$

Correlation of Normal Serum and Psychotic Serum Readings:

$$\text{Validity or critical ratio} = \frac{D}{P. E. \text{ diff.}} = 25$$

Since according to recognized mathematical criteria a critical ratio of 3.0 or more indicates that the difference between averages is a significant and not a chance difference, it will be seen that all the experiments analyzed to determine the standard deviation, probable error, and probable error of difference yield critical ratios of a much higher order and, therefore, reveal results of very high significance and reliability indeed.

ANALYSIS OF INTERGROUP VERSUS INTRAGROUP VARIATIONS BY FISHER'S METHOD

To further test the reliability of the foregoing data special analysis was made of the readings obtained for intergroup versus intragroup variations according to Fisher's well-known method.

Analysis of Variance.—Fundamentally analysis of variance is a test of significance. It is based on the solution of a number of problems of statistical distribution obtained by Fisher.¹⁹ The total variation in this experiment is separated into two parts, viz. (1) the variation attributed to irregularities in the results obtained in the given group, and (2) the variation attributed to the difference between the mean performances of the different groups. Once these two variabilities have been separated, they are compared to see whether or not there is a significant difference between them. In this way it can be determined whether the variation within the group is significantly greater or less than the variation between groups.

1. *Variation Within the Group.*—(a) The sums of the squares of the deviations from the individual means are computed. In this case they are:

Shive solution	=	200.960
Normal blood sera	=	181.090
Pemphigus blood sera	=	96.000

(b) The sums of these squares pooled are equal to 478.050. (c) The variance from this source is estimated by dividing the pooled sums of the squares by the degrees of freedom. The latter is the product of the number of group and one less the number of trials, i.e., $3 \times 49 = 147$. Thus the estimate of variance is $478.050/147 = 3.252$.

2. *Variation Between Groups.*—(a) The sum of the squares of the deviations of the sums from the mean of the sums is computed. Since the latter is the sum of the sums over 3 = 472.33, the step is as follows:

$$(496 - 472.33)^2 + (661 - 472.33)^2 + (260 - 472.33)^2 = 79.155$$

(b) This sum is divided by the number of trials per subject to reduce the sum of squares to a per item basis; thus $79.155/50 = 1.5831$. (c) The variance is estimated from this source by dividing the reduced sum of squares by the degrees of freedom of groups, i.e., by $n - 1 = 2$; thus $1.5831/2 = 0.79155$.

TABLE VII

COMPARISON OF READINGS OBTAINED WITH SEEDLINGS GROWN IN (1) SHIVE SOLUTION AND IN SOLUTIONS OF (2) NORMAL HUMAN BLOOD SERUM AND OF (3) PEMPHIGUS SERUM

SEEDLING	GROUP			TOTAL

44	16	11	6	
45	12	10	5	
46	14	10	5	
47	14	10	3	
48	13	10	5	
49	11	12	5	
50	15	9	7	
Sums	661	496	260	1417
Means	13.22	9.92	5.20	28.34
Σ (deviations from means) ²	200.960	181.090	96.000	478.050

3. *Application of the F Test.*—This is that method described by Fisher²⁰ as "testing whether one estimate of variance derived from n_1 degrees of freedom is significantly greater than a second such estimate derived from n_2 degrees of freedom." A convenient adaptation is supplied by Mahalanobis²¹ and Snedecor.²² There are two steps in this test: the first is to form the ratio of the greater to the lesser variance, i.e., $791.55/3.252 = 243.5$; the second is to match this value in Fisher's table for the distribution of F, a table which shows how high the ratio must be to be barely significant and highly significant. It is entered with the degrees of freedom of the two variances forming the ratio. In evaluating the significance of the two degrees of freedom in this experiment, as outlined above, the figure 3.06 is regarded as barely significant and the figure 4.75 as highly significant. Thus the ratio of 243.5, which is far in excess of the higher ratio of 4.75, shows that the difference between the groups in this experiment is very significant indeed and greater than that within the groups.

COMPARISON OF READINGS OBTAINED WITH SEEDLINGS GROWN (1) IN SHIVE SOLUTION ALONE, (2) IN SHIVE SOLUTION WITH 1 PER CENT NORMAL BLOOD SERUM, AND (3) IN SHIVE SOLUTION WITH 1 PER CENT X-RAY BLOOD SERUM

	SHIVE SOLUTION	NORMAL BLOOD SERUM	X-RAY BLOOD SERUM
Sum	661	496	298
Mean	13.22	9.92	5.96
Σ deviations ²	200.96	181.09	203.89

Sum of deviations² = 585.94. Degrees of freedom = $3 \times 49 = 147$. Variance = $585.94/147 = 3.99$.

Sum of the sums = $661 + 496 + 298 = 1455$. Average = $1455/3 = 485$.

$$(661 - 485)^2 + (496 - 485)^2 + (298 - 485)^2 = 66066$$

$$66066/50 = 1321.32$$

$$1321.32/2 = 660.66$$

$$660.66/3.99 = 165.3$$

$$\text{Ratio of greater to lesser variance} = 165.3.$$

Thus it will again be seen that the intergroup difference is significantly greater than the intragroup difference.

COMPARISON OF READINGS OBTAINED WITH SEEDLINGS GROWN (1) IN SHIVE SOLUTION ALONE, (2) IN SHIVE SOLUTION WITH 1 PER CENT NORMAL BLOOD SERUM, AND (3) IN SHIVE SOLUTION WITH 1 PER CENT BLOOD SERUM FROM A PSYCHOTIC PATIENT

$$\text{Variance} = 3.79$$

$$\text{Sum of sums} = 661 + 496 + 298 = 1455$$

$$\text{Mean} = 1455/3 = 485$$

$$(661 - 485)^2 + (496 - 485)^2 + (298 - 485)^2 = 66066$$

$$66066/50 = 1321.32$$

$$1321.32/2 = 660.66$$

$$660.66/3.79 = 174$$

$$\text{Ratio of greater to lesser variance} = 174.$$

Again it will be observed that the intergroup difference is very significantly greater than the intragroup difference.

These detailed analyses of data obtained in typical experiments with control solutions in plant physiologic saline, on the one hand, and with normal serum and blood sera obtained from patients with pemphigus, x-ray therapy, and grave psychoses, on the other, leave no doubt as to the reliability of the

phytopharmacologic technique, as practiced in this laboratory, and the positive significance of the data obtained thereby. This, of course, applies to the phytopharmacologic test as employed by an experienced worker in the field. While our statistical analysis was made on long-range experiments, i.e., experiments in which 50 seedlings were employed for each solution studied, Macht and his co-workers have discovered in actual clinical practice that reliable data regarding the phytotoxic properties of blood sera are obtained by means of a smaller number of seedlings. The routine procedure in this laboratory is to employ ten healthy seedlings for each solution and to repeat the experiment on two or three successive days. If the phytotoxic indices derived from the successive experiments vary by no more than 5 per cent, the average figure obtained has been found to be very reliable as it almost invariably agrees with the final diagnosis of the blood picture made independently by the clinical practitioner and pathologist who forward the sample for pharmacologic study.

SUMMARY

1. The Macht technique for determination of phytotoxic reactions of blood sera is described in detail.

2. Tables presenting the phytotoxic indices obtained in phytopharmacologic examination of numerous toxic, nontoxic, and atoxic blood sera are offered for use as criteria in carrying on further work of this kind.

3. A biometric analysis of data obtained in typical experiments with normal human blood serum and blood sera from persons with pemphigus, x-ray therapy, and grave mental disease is made in detail to illustrate the reliability of the phytopharmacologic test and the significance of results secured by this means.

4. The various data adduced demonstrate the utility of the phytopharmacologic test or the application of plant physiology to investigation of clinical problems.

CLINICAL AND EXPERIMENTAL

SULFAPYRIDINE IN EXPERIMENTAL BRUCELLOSIS*

E. S. KING, M.D., F.A.C.P., AND MARGARET LUCAS, A.B., M.T.
WAKE FOREST, N. C.

WITH the advent of sulfapyridine in the field of therapeutics, especially in the treatment of pneumonia, a disease in which it produces such remarkable beneficial results, it was perhaps to be expected that it would be tried in the treatment of many other diseases, and to be hoped that it would show the same remarkable curative value in some of them as in pneumonia. Likewise, its ability to prevent and cure pneumococcal infections in experimental animals has been demonstrated many times by many investigators. Little has appeared in the literature so far reporting experimental results with this drug in the treatment of *Brucella* infections. On the contrary, many reports of the results of experimental work with regard to treating these infections with sulfanilamide are available. Many investigators have also reported various degrees of satisfactory results in the treatment of human brucellosis with sulfanilamide and its derivatives. Since the two drugs, sulfanilamide and sulfapyridine, are so closely related chemically, it is reasonable to expect them to show certain similarities in their therapeutic properties and that sulfapyridine might show even a better result in the treatment of these diseases.

Chinn¹ in a recent article reports that sulfanilamide has both preventive and curative effect on guinea pigs inoculated with *Br. abortus*, *Br. melitensis*, and *Br. suis*. Menefee and Poston² also report good results in the treatment of *Br. melitensis* var. *melitensis*, *abortus*, and *suis* with sulfanilamide.

To our knowledge no previous report on work with sulfapyridine in experimental *Brucella* infections of guinea pigs has been published.

The present report deals with results that were obtained with a group of guinea pigs after their experimental infection with the three *Brucella* organisms named above, as well as with the in vitro tests using the same organisms.

METHOD

The cultures used in this work were kindly supplied by Dr. I. F. Huddleson,³ of the Michigan State College of Agriculture. We found that these organisms grew well on meat extract agar, but resulted in a more abundant growth on beef liver infusion agar. Because they did not require increased carbon dioxide tension for growth, we did not use this method in any of our cultures.

*From the Department of Bacteriology and Preventive Medicine, Wake Forest College School of Medical Sciences.

Received for publication, November 29, 1939.

IN VIVO TESTS

We injected intraperitoneally 56 male guinea pigs of about the same age and size and divided them into three groups. The dose of organisms given each animal was one-half of a beef liver infusion agar slant suspended in normal saline solution. Normal saline solution slightly in excess of 2 c.c. was placed in the culture tube, and the organisms were stirred into an even suspension. One cubic centimeter was injected; therefore, one culture made two doses. Of the group of 56 guinea pigs, 16 were injected with *Br. melitensis*, 16 with *Br. abortus*, and 24 with *Br. suis*. These groups were subdivided into groups as follows: four, six, two, and four for each of the *Br. melitensis* and *Br. abortus*; and five, nine, four, and six for the *Br. suis*. The groups of four, four, and five in the case of each organism were given 100 mg. of sulfapyridine daily, orally, beginning one and one-half hours after the injection. The groups six, six, and nine in each organism were given 200 mg. of the drug by mouth daily beginning six days after the injection. The groups two, two, and four were given 100 mg. of sulfapyridine subcutaneously suspended in distilled water. In the groups four, four, and six no drug was given, and these animals served as controls. The drug was given once daily in a single dose in all instances by mouth, except as indicated above. The treatment was terminated at the end of three weeks in all groups. During the three weeks' period of treatment 15 animals died; therefore, the autopsy report contained 41 animals. The oral administration of the drug was accomplished with ease by giving a broken piece of the tablet rather than the powder. The animals receiving the drug beginning one and one-half hours after the injection were for the purpose of determining its preventive value, while from the group in which the drug was begun six days after injection we hoped to determine its curative effect. At the end of the treatment period all the animals were killed except half of the groups six, six, and nine. These were kept living for twenty-one days longer to determine by comparison with the other members of this group whether there occurred a flare-up of any hidden or latent infection. During the period of treatment all animals looked fairly normal except for a small per cent that appeared sick, some of which died. The greatest mortality rate occurred in the *Br. suis* group.

At autopsy the abdominal organs were noted for obvious pathology. No sections for microscopic study were made. In some of the animals gross evidence of disease was obvious in the form of small abscesslike lesions on the surface of the liver. There was also seen in some animals tough, exudative adhesions between the intestines and liver, liver and abdominal wall and intestines. The liver and spleen in all animals were weighed and were found in most cases not to exceed the normal weight. The average weight in the treated group of the spleen was 1.19 Gm. and of the liver 29.32 Gm. In the control group the average weight of the spleen was 1.12 Gm. and of the liver 30.46 Gm.

Beef liver infusion agar cultures were made from the sectioned liver and spleen from each animal. In a few instances cultures from the heart's blood were also made, but these were not completed. Since doing this work we attended a symposium on "Brucella Infection and Hodgkin's Disease" at Duke

University Medical School, participated in by Forbus, Poston, Gunter, and Wise, who report that the primary seat of involvement in experimental guinea pig infections with these organisms is found in the lymph glands. In our animals we did not notice any lymphadenopathy.

The cultures were examined after one week's incubation at 37° C. and evidence for positiveness was made by naked eye examination and Gram-stained smears. Table I summarizes these findings.

TABLE I

IDENTIFICATION MARK OF ANIMALS	SUIS			MELITENSIS			ABORTUS

*Each check indicates negative or positive culture findings and also each check under liver column represents one guinea pig.

IN VITRO TESTS

In order to determine the bactericidal (lethal) effect of sulfapyridine when mixed in broth cultures with the organism we followed this technique:

A forty-eight-hour beef liver infusion broth culture was prepared and a portion of this diluted 1:100. One-tenth cubic centimeter of this dilution was placed in each of five flasks containing 100 c.c. of beef liver infusion broth. To the first of these 100 mg. of sulfapyridine were added, giving a concentration of the drug of 1:1,000. A sterile 100 mg. per cent solution of sulfapyridine was prepared and to the second flask 10 c.c. were added, giving a drug concentration of 1:10,000; to the third flask 1 c.c. was added, giving a concentration of 1:100,000; to the fourth flask 0.1 c.c. was added, giving a drug concentration of 1:1,000,000; no drug was added to the fifth flask which served as a control. Immediately after mixing the organisms and drug, pour plates were made, using 0.1 c.c. of the drug-organism mixture and beef liver infusion agar as the pour medium. This was repeated at intervals of ten minutes: twenty-four, forty-eight, and seventy-two hours. After seven days' incubation of the pour plates counts were made with the results shown in Table II. The counts showed that the drug in 1:1,000 and 1:10,000 concentrations had definite or complete bactericidal power against *Br. melitensis* and *Br. suis*, but these

concentrations showed only definite bactericidal or bacteristatic effect against *Br. abortus*. In the 1:100,000 and 1:1,000,000 drug concentrations some bactericidal effect was noted against all organisms.

TABLE 11

PERIOD OF INCUBATION	NO DRUG	SULFAPYRIDINE 1:1,000	SULFAPYRIDINE 1:10,000	SULFAPYRIDINE 1:100,000	SULFAPYRIDINE 1:1,000,000

*These figures are actual plate counts of bacteria per 1 c.c. of the different cultures.

CONCLUSIONS

We conclude from the results of this work that sulfapyridine in treating experimental brucellosis in the method employed in these experiments showed only a slight preventive or curative effect. However, we do think that it is significant that in the group of animals receiving 200 mg. there was not a single animal showing pathologic evidence or a positive culture, except in the group that was held over for quiescent infection determination. A glance at Table I will show that two groups of these were positive. This would seem to indicate that the infection was being held under control by the drug and underwent a flare-up after it was discontinued. We are aware of the fact that sulfapyridine, as given in this experiment, was not administered as frequently as is desired, yet the size of the largest dose when based on body weight, which is the usual way of computing dosage, is about eight to ten times larger than the average size for human beings, and this might in some way compensate for less frequent administration.

Armstrong and Muirhead⁴ recently reported that in a large series of guinea pigs 100 mg. of sulfapyridine orally every four hours maintained blood drug concentration at about the 7 mg. per cent level. Further, they report that 50 mg. orally every four hours did not keep the level up to what is generally considered to be optimum, while 200 mg. every four hours kept the level above the optimum of about 7 mg. per cent. On the basis of this work, we have reason to believe that after the drug was given in our animals the blood concentration reached about a 6 mg. per cent to a 15 mg. per cent level and then gradually fell before the next dose.

In our in vivo tests the drug seemed to show best results in *Br. suis* infections and poorest results in *Br. abortus*. In the animals held over for twenty-one days longer without treatment for evidence of latent or hidden infection, we found heavy infections in both *Br. suis* and *Br. abortus* animals and negative pathologic and cultural evidence with *Br. melitensis* animals.

The in vitro tests showed that in the 1:1,000 and 1:10,000 concentrations against *Br. suis* the drug resulted in complete destruction of the organism. In the 1:100,000 concentration against this organism definite bactericidal effect was noted, while the 1:1,000,000 dilution showed only feeble destructive power. These findings are in agreement with the in vivo findings, since it was in *Br. suis* infection that best results were noted. Against *Br. melitensis* the 1:1,000 drug concentration showed complete bactericidal power; the 1:10,000 nearly complete killing power; the 1:100,000 concentration definite destructive power; and the 1:1,000,000 concentration showed no killing power. The effect of the drug against *Br. abortus* was different when compared with the other two organisms. This organism was far more resistant; the 1:1,000 concentration showed a definite bactericidal effect only and the remaining dilutions showed less effect as the drug concentrations were reduced. In other words, the drug had far less killing power against *Br. abortus* when compared with its killing power against *Br. suis* and *Br. melitensis*. Therefore, it appears that in the therapy of these infections the drug is more potent against *Br. suis* infection, less potent against *Br. melitensis*, and least potent against *Br. abortus*.

SUMMARY

1. Three groups of normal healthy guinea pigs were each injected with *Br. suis*, *Br. melitensis*, and *Br. abortus*.

2. The dose of organisms used was one-half of a beef liver infusion agar slant culture.

3. Each main group of injected animals was divided into four subgroups and each subgroup was treated as follows: one subgroup was given 100 mg. of sulfapyridine daily by mouth, beginning one and one-half hours after injection; one was given 200 mg. of the drug daily by mouth, beginning six days after injection; one was given 100 mg. of the drug subcutaneously, beginning six days after injection; and one was not given any drug and served as a control group.

4. All treatment was terminated twenty-one days after injection.

5. At the end of this treatment period all animals were autopsied, except half of each of the groups receiving 200 mg. These were held for twenty-one days longer to determine whether a flare-up of the infection occurred during the no drug period.

6. The drug used for the in vitro tests was a 100 mg. per cent solution in distilled water. This was suggested by Dr. Robert Hoyt,⁵ of the University of Minnesota, who reported that he found a 100 mg. per cent solution satisfactory for general use.

7. The medium used throughout was beef liver infusion broth and agar. This medium was selected because it seems to possess certain nutritional substances promoting growth of these organisms.

8. The cultures used in these experiments were obtained from Dr. Huddleson, of Michigan State College.

9. We feel that the drug in the method used does not control or cure *Brucella* infections in guinea pigs, in spite of the fact that based on body weight the amount given was far greater than the usual (80 grains a day) therapeutic amounts given human beings. We believe that the drug has curative value against at least two of the types of *Brucella* infection (*Br. suis* and *Br. melitensis*) when given frequently enough to maintain a constant blood level.

CHANGES IN THE SEDIMENTATION RATE AND NONFILAMENT-FILAMENT RATIO FOLLOWING CLINICAL IMPROVEMENT IN PATIENTS WITH LOW-GRADE CHRONIC ILLNESS

A STATISTICAL ANALYSIS OF 323 CASES

MERRITT H. STILES, M.D., PHILADELPHIA, PA.

IN A STUDY of patients with low-grade chronic illness, in which chronic infection appeared to play an important part,¹ it was reported that (a) practically all patients showed an increased nonfilament-filament ratio; (b) more than 80 per cent showed an increased sedimentation rate; (c) the nonfilament-filament ratio and the sedimentation rate were higher in patients with severe symptoms than in those with moderate or mild symptoms; and (d) in acute exacerbations the nonfilament-filament ratio was increased relatively more than was the sedimentation rate. The present study was made to determine the character and extent of the changes in the nonfilament-filament ratio and the sedimentation rate which were associated with clinical improvement or recovery in a similar group of patients.

CLINICAL DATA

Studies of the blood were made on 323 patients with chronic or frequently recurring symptoms, many of which were probably secondary to low-grade chronic infection. Patients were grouped according to severity of illness, as having mild or recurrent, moderately severe, or severe symptoms. An additional group included patients with more or less acutely increased symptoms. Detailed analysis of a similar series of patients as to age, sex, and clinical diagnosis have been reported.¹

Following definite clinical improvement, whether spontaneous or following treatment, the blood studies were repeated. Improved patients were grouped as symptom free, or as having mild or moderate symptoms. Patients were also grouped according to the degree of improvement, from mild to symptom free, from moderate to mild, or from severe to moderate being considered as one stage; from moderate to symptom free or from severe to mild as two stages; and from severe to symptom free as three stages of improvement. The group of patients with acutely exacerbated symptoms was not included in this analysis because the nonfilament-filament ratio and the sedimentation rate did not conform to relationships found in other groups.¹

METHODS

Sedimentation rate determinations and complete blood counts were made on all patients. Except for nonfilament-filament ratios, hematologic data will not be discussed because the changes were inconstant or infrequent. In making differential counts neutrophils in which two or more lobes were united only by a filament of chromatin were recorded as filamented cells, others were classified as nonfilamented. The ratio of nonfilamented to filamented neutrophils (referred to as nonfilament-filament ratio) was expressed in percentage, i.e., nonfilament-filament ratio = $\frac{\text{nonfilamented cells} \times 100}{\text{filamented cells}}$.

In determining the sedimentation rate oxalated blood was drawn up to the 200 mm. mark on a Westergren tube. At the end of one hour the height of the column of clear fluid was recorded in millimeters.¹

TABLE I

CHANGES IN THE SEDIMENTATION RATE AND NONFILAMENT-FILAMENT RATIO IN PATIENTS SHOWING CLINICAL IMPROVEMENT

FINDINGS	PATIENTS	RANGE	MEAN	STANDARD DEVIATION	STANDARD ERROR
<i>Original</i>					
Nonfilament-filament ratio	299	10-100	29.75	14.34	0.83
Sedimentation rate	200	2-99 mm.	21.15	18.05	1.275
<i>Following improvement</i>					
Nonfilament-filament ratio	299	4-24	10.26	5.18	0.3
Sedimentation rate	200	1-35 mm.	6.425	5.85	0.41

Table I shows a comparison of the sedimentation rates and nonfilament-filament ratios, both originally and after definite improvement. The mean nonfilament-filament ratio of 299 patients was 29.7 originally and 10.3 following definite improvement. Although some of the patients showed higher ratios after improvement than did others originally, the difference between the mean values before and after improvement was 18.3 times its standard error. The mean sedimentation rate of 200 patients was 21.15 mm. originally and 6.42 mm. following improvement. The difference between the two mean values was 11.4 times its standard error.

As noted previously, patients were classified according to the number of stages of improvement (Table II). The reduction in the mean nonfilament-filament ratio was 40.7 in patients with three stages of improvement, 22.4 in

those with two stages, and 12.0 in those with one stage. The mean sedimentation rate was reduced 35.7 mm. in those with three stages, 18.4 mm. in those with two stages, and 7.5 mm. in those with one stage of improvement.

The relationship between improvement in clinical and laboratory findings was less constant in patients with only one stage of improvement, two patients in this group showing slightly higher nonfilament-filament ratios after improvement, and seven showing either no change or a slight increase in the sedimentation rate.

The differences between the mean gains shown by the various groups were all statistically significant.

TABLE II

RELATIONSHIP BETWEEN CHANGES IN THE SEDIMENTATION RATE AND NONFILAMENT-FILAMENT RATIO AND THE DEGREE OF CLINICAL IMPROVEMENT

DEGREE OF IMPROVEMENT	PATIENTS	RANGE	CHANGE IN VALUES		
			MEAN	STANDARD DEVIATION	STANDARD ERROR
1 stage					
Nonfilament-filament ratio	137	+3 to -29	-11.08	4.97	0.425
Sedimentation rate	94	+3 to -29 mm.	- 7.81	6.94	0.715
2 stages					
Nonfilament-filament ratio	113	-1 to -49	-22.38	9.33	0.88
Sedimentation rate	69	0 to -69 mm.	-18.44	13.88	1.67
3 stages					
Nonfilament-filament ratio	39	-17 to -75	-40.69	12.18	1.95
Sedimentation rate	26	- 5 to -94	-35.69	22.1	4.84

CONCLUSIONS

Clinical improvement in patients with low-grade chronic illness is accompanied by statistically significant improvement in the sedimentation rate and nonfilament-filament ratio.

The degree of improvement in the sedimentation rate and non-filament-filament ratio varies significantly with the degree of clinical improvement.

BRONCHIECTASIS ASSOCIATED WITH MONILIA SIMULATING PULMONARY TUBERCULOSIS*

A CLINICAL-PATHOLOGIC STUDY

E. ROBERT WIESE, M.D., WHITE HAVEN, PA., AND E. W. BIXBY, M.D.,
WILKES-BARRE, PA.

BRONCHIECTASIS, because of the problems relative to etiology, prognosis, pathology, and treatment, has been a subject of interest to medical men from the time of its first description by Laënnec to the present day. Regarded as a comparatively rare disease when only autopsy material was available, the modern use of radio-opaque substance has shown the condition to be more prevalent than formerly believed, and both medical and surgical interest has correspondingly increased. Without the use of such radio-opaque substances the diagnosis is not easy, and its chronicity, complications, and verisimilitude to other pulmonary diseases has frequently led to errors in diagnosis. Infection of the bronchiectatic dilations by nearly all the microorganisms found in pulmonary disease is almost a logical sequence of events and has been the subject of several papers and discussions by many men. The following is submitted as a peculiar infection in a well-defined case of bronchiectasis, erroneously diagnosed as pulmonary tuberculosis.

E. W., a white, unmarried woman of 30 years, entered the White Haven Sanatorium on April 4, 1938, with a diagnosis of pulmonary tuberculosis in the service of one of us (E. W. B.). Except for the fact that her father had died of carcinoma of the stomach in 1912, the family history was negative. Her past history included an attack of influenza in 1919, two attacks of pleurisy without effusion and bronchitis previous to 1936, and numerous colds. There was no history of whooping cough or of any contact with tuberculosis. The present illness began in April, 1936, with a pulmonary hemorrhage of 8 ounces. After approximately three months' rest at home, the patient went to a private sanatorium from July to October, 1936, but returned to work as a stenographer on November 1 of that same year. She did well until March 7, 1938, when she had a second severe and protracted hemorrhage of approximately 24 ounces. A few days afterwards x-rays of the chest were taken and sputum tests were made. Although no tubercle bacilli were found in the sputum, the patient was diagnosed as having pulmonary tuberculosis on the basis of the history, clinical evidence, and x-ray findings—a perfectly reasonable assumption. Her account of the cough of which she complained was interesting. She was quite definite in her statement that the many "colds" with which she was afflicted began in April, 1935, a year before her first hemorrhage. She had coughed ever since that date; her sputum was an odorless, yellowish green fluid, and varied in amount from 1 to 4 ounces daily. Despite many tests, no tubercle bacilli were demonstrated.

*From the Medical Department of the White Haven Sanatorium, White Haven, Pa.
Read before the Luzerne County Medical Society, Wilkes-Barre, Pa., November, 1, 1939.
Received for publication, November 30, 1939.

Upon admission the patient was a rather sickly appearing pale woman. The right side of her chest, somewhat smaller than the left, did not expand freely. The quality of the percussion note increased from impairment in the upper part to distinct dullness at the base where there was a suggestion of a pleural rub. The whispered voice was increased throughout the entire right side of the chest; the breath sounds were bronchial in character and coarse râles, especially at the base, were present. The left side of the chest was a trifle full and expansion was good; the percussion note was impaired in the upper part where the whispered voice was somewhat increased and the breath sounds were bronchovesicular in character. Otherwise the left side of the chest was negative. The cardiac point of maximum impulse was found in the fifth intercostal space inside the midclavicular line. No cardiac murmurs were heard. The fingers were not clubbed, nor were the nails curved. The blood pressure upon admission was 116/80, the red blood cell count was 4,400,000, the white blood cell count was 10,200, of which 68 per cent were polymorphonuclear cells and 30 per cent lymphocytes. The hemoglobin was 80 per cent and the Wassermann test was negative. Repeated sputum examinations were, and continued to be, negative for Koch's bacillus. The urinalysis was negative. Examination by Dr. Joseph C. Donnelly, of Philadelphia, revealed infection of the left maxillary sinus. The x-ray report of April 15, 1938, read as follows:

"The left lung is essentially normal. The shadows over the lower portion of the right lung are evenly increased in density, and there is a distinct atrophy of the right side of the chest indicative of a bronchial occlusion. The etiological factor is not clear, but if the sputum be negative, I would be suspicious of a benign growth. A pneumonography and a bronchoscopic examination may throw some further light on the condition." (Fig. 1.)

The last sentence in this report strengthened our determination to use some radioactive substance to determine the presence or absence of a condition we had previously suspected from a study of the history, clinical findings, and x-ray films on the case. Lipiodol was introduced into the trachea by the intertracheothyroid route on May 16, 1938, and the x-ray report read as follows:

"The iodized oil has entered the bronchial branches of the right lower and I believe the right middle lobe. It has collected in pools in cylindrical dilatations along the bronchi. The changes are those of a bronchiectasis involving particularly the lower lobe and I suspect there is also some involvement of the middle lobe." (Fig. 2 and Fig. 3.)

The patient's temperature, 101° F. upon admission to the White Haven Sanatorium, became normal under the influence of bed rest. Her pulse, 108 when the patient was first seen, also became normal under a like treatment. She weighed 94 pounds when she first came to the White Haven Sanatorium and gained 25 pounds in the next six months (119 pounds).

Even before the diagnosis of bronchiectasis was thus made, a number of yeastlike cells were discovered in the sputum during the continuous search for the tubercle bacilli. A culture medium of glucose, powdered raw potato, peptone, and agar was inoculated with the sputum and cultivation was carried on at room temperature. An organism which closely resembled *Monilia albicans* (Castellani) was identified by morphologic, structural, and cultural characteristics. The cells, either round or somewhat oval in shape, varied in size; the mycelium was septate and conidia were formed both by budding near the joints and abstriction at the ends of the hyphae. The culture characteristics were tested in a strained medium made up of peptone, powdered raw potato, and water; to this were added in different fermentation tubes dextrose, maltose, lactose, galactose, levulose, dextrin, and monnite—a separate sugar to each tube; aqueous acid fuchsin (0.5 per cent) was used to

determine the formation of acid during the growth of the fungus in these tubes during the next two or three weeks at room temperature. Gas and acid formation were observed in the tubes containing dextrose, levulose, maltose, and galactose in three successive cultures during the next ten weeks. The organism was identified as *Monilia albicans* (Castellani).

Our inability to discover any evidence of thrush in the mouth or pharynx was confirmed by Dr. M. J. Hess (D.D.S.) of White Haven, who cleared the mouth of all objectionable or suspicious elements. The gums were thoroughly healed before work was begun upon the sputum, and the patient was instructed to use a strong mouth wash before expectorating—a precept which we are certain she rigidly followed.

Fig. 1.

COMMENTS

Because of the generally accepted opinion of medical men that the disease is one seen only by those engaged in tropical medicine—and possibly also because of the little space devoted to the subject in even the best textbooks on diseases of the lung—fungus infection of the respiratory tract has received little attention to the present time from the medical profession of the temperate zone. A growing literature within the past fifteen years, however, has aroused interest in the disease, and has placed among diagnostic possibilities a condition that may not only simulate especially the more chronic diseases of the lung, but may affect the prognosis when seen as a complication and may even cause death.

Fig. 2.

Fig. 3.

Classification of the microorganisms included in the subject of mycology is in a state of almost hopeless confusion. Almost any one of the authorities seems to mention the classification proposed by another authority only to differ from it and to propose his own classification in its stead. One authority, indeed, goes so far as to suggest the scrapping of all classifications thus far proposed and to include all fungi under the general heading of blastomyces. Nor do they agree as to methods. Castellani, for example, although admitting the occasional failure of the procedure, lays stress upon the ability of the microorganisms to ferment the various sugars and to produce acid in the different solutions as a means of identification. Dodge, on the other hand, scouts the idea and seems to rely solely upon the morphology of the microorganism in question. Even the biological relationship between monilia, oidia, torula, and yeasts is not a settled thing among various authors, although almost without exception they classify the monilia among fungi imperfecta.

Irrespective of classification, however, all authorities agree that fungus infection of the lung is possible and divide the cases into three types. In the mild type of infection the general condition of the patient is not much impaired. There is little or no fever; the sputum is generally scanty and mucopurulent in character; a few râles may be heard but usually examination of the chest is negative. In the intermediate type there is evidence of a mild catarrhal bronchitis; a slight fever is usually found; the cough, differing in character in different patients, is usually paroxysmal and, as a rule, is most severe in the morning and the evening. Dyspnea is not infrequently one of the symptoms. In the severe type the patient loses weight, the fever is hectic, the sputum is rather profuse, and at times hemorrhagic; night sweats and a marked anemia are very often found. Chest examination reveals areas of dullness, fine râles, and evidences of pleuritis; in short, the picture of the severe type closely resembles that of pulmonary tuberculosis, for which it may be readily mistaken. The prognosis naturally varies with the virulence of the infection. The mild type may clear up spontaneously or after several weeks or months may develop into the intermediate or the more severe type; it usually yields to treatment. The intermediate type is more stubborn, and the response to treatment is often slow. The therapy must be continued, as such cases may readily develop into the third type. The severe type is often difficult to combat, and cases of death due to mycotic infection of the lung are not wanting (Stovall and Greeley, Warr).

The x-ray film in this disease also closely resembles that of pulmonary tuberculosis. There may be peribronchial thickening, nodules, infiltration, pleural thickening, areas of consolidation, and even fibrosis shown in the film (Bakst, Hazard, and Foley). The apices usually remain clear even in the most advanced cases, the disease being essentially a basal one (Balog and Grossi). Little is known of the pathologic findings in man, as few autopsies have been reported. In the case cited (Warr) both right and left lungs were adherent to the chest wall; there were numerous cavities on each side, and the lower lungs were consolidated and easily torn. The cut surfaces were glistening, shiny, and translucent. Both lungs were greatly reduced in size with little air-bearing space in either. Potassium iodide seems of value in the treatment of the disease,

especially of the first and second types. Castellani advocates the administration of 15 grains of potassium iodide in milk or water three or four times a day over a period of three to four weeks. Other medication has also been lauded. Balog and Grossi favor the use of insulin, Stovall and Greeley gave gentian violet intravenously. Thymol also has its advocates. Vaccine treatment has been proposed, and Kotkis, Wachowiak, and Fleisher, for example, reported complete disappearance of symptoms in one case and marked improvement in another. Balog and Grossi are of the opinion that vaccine treatment is the sole therapy capable of restoring the injured myocardium in moniliasis. Craik reports the successful use of alkalis, adrenalin, and potassium iodide. The roentgen ray as a therapeutic means has been used by Schmidt and Howe. Warr classes alkalis and iodide by mouth, and autogenous vaccines and ultraviolet rays as energy providers.

SUMMARY

A case of bronchiectasis in conjunction with *Monilia albicans* has been reported, together with a brief discussion on mycotic infection of the respiratory tract. We are of the opinion that mycotic infection of the respiratory tract is of more frequent occurrence than is generally believed, and that careful search of cases closely simulating pulmonary tuberculosis in the absence of tubercle bacilli in the sputum will reveal this condition, especially where the lesion is of the basal type.

In conclusion, may we say that we do not wish to leave the impression that we believe that *Monilia* was in any way responsible for the bronchiectasis, but rather that the bronchiectasis offered a very favorable soil for the growth of the fungus when once it had reached the lung. Another point worthy of note is that bronchiectasis and moniliasis, both pre-eminently basal affections of the lung, individually closely simulate basal pulmonary tuberculosis. The combination of the two diseases certainly more than doubles the resemblance. The fact that the specimens were not obtained directly with the bronchoscope need not militate against the results as all possible means were taken to eliminate oral contaminations. If this failure is a fault, then it is one shared by all cases we found in literature.

Comments by Dr. E. W. Bixby: The history of the case to date is also interesting. After it had been determined by all the usual tests (including animal inoculation) that the patient was not suffering from pulmonary tuberculosis, she was removed from the White Haven Sanatorium on November 19, 1938, to a hospital in Wilkes-Barre, where her accessory nasal sinuses were thoroughly drained. Ten bronchoscopic drainages were also done at the same hospital. She was then transferred to the Pennsylvania Hospital, Philadelphia, in the latter part of June, 1939, where Dr. John B. Flick removed the lower lobe of the right lung. Because of the many and dense adhesions present, the operation was a very prolonged and difficult task, but the patient withstood the operation well and made an uneventful recovery until August 15, 1939, at which time she developed an empyema. Closed drainage was instituted and a recent letter from Doctor Flick reports the patient in good condition.

PRIMARY MALIGNANT TUMORS OF THE SPLEEN WITH REPORT OF A CASE OF LYMPHOSARCOMA*

CHARLES W. BONNEX, M.D., PHILADELPHIA, PA.

THE infrequency of primary malignant tumors of the spleen affords sufficient reason for reporting single cases as they occur in the practice of individual surgeons, or as they are found on the autopsy table by pathologists. Examination of the literature shows that very few surgeons have removed more than one tumor of this kind; and in this connection it may be stated that the case here reported is the only one to be found in the records of the Jefferson Medical College Hospital.

In 1929 Tasker Howard,¹ of Brooklyn, found 115 cases recorded in the literature and added another case that had occurred in his own practice. Since the publication of Howard's paper, I have succeeded in finding 23 more evidently authentic cases²⁻²² which, with the one here reported, brings the total number of cases to 140.

Because of the rarity with which these cases occur, and also because of the complex structure of the spleen, classification of the tumors has been difficult. Growths called carcinoma have been reported, but the histologic structure of the spleen renders the development of a primary epithelial growth impossible, unless it is of the fetal inclusion type.

Various names have been applied to tumors of the connective tissue type, and even at the present time it would seem that a definite classification has not been firmly established. For instance, as late as 1935, Stevenin¹⁷ and his associates studied a tumor, which, they stated, could not be placed in any of the classifications previously made. Because of its resemblance to undifferentiated reticular sarcoma of bone marrow, they finally decided to call it undifferentiated reticular sarcoma.

Without reviewing the various classifications, it may be stated that a primary malignant neoplasm may take origin from the connective tissue in the splenic capsule; from the reticular stroma of the spleen; from the endothelial

*Presented in Abstract at the Ex-Internes and Class Reunions Clinic, Jefferson Medical College Hospital, May 31, 1939.

Received for publication, December, 1, 1939.

cells in the walls of the blood vessels; from the reticulo-endothelial cells lining the splenic sinuses; and from the lymphoid tissue surrounding the arterial vessels as an interrupted sheath, known as the splenic nodules or Malpighian corpuscles. The endothelial and lymphoid types are apparently the most common, the latter being termed lymphosarcoma. Vascular growths known as malignant hemangioma, hemangiosarcoma, and hemangio-endothelioma are also of relatively frequent occurrence.

The case that I am now reporting is that of a man, who at the time I operated upon him, January 5, 1928, was 58 years old. His history prior to the development of the splenic tumor is not without interest, in that it shows a susceptibility to disease of the reticulo-endothelial system. On two occasions, first in 1909 and again in 1921, enlarged lymph nodes were removed from the inguinal and cervical regions, respectively. In the interval of twelve years between the two operations, and also after the second operation, no evidence of enlarged lymph nodes was noticed in any part of the body.

Unfortunately, no record of microscopic examination of the inguinal nodes removed in 1909 was obtainable. Dr. Baxter L. Crawford, who examined the discrete cervical nodes removed in 1921, stated that the histologic picture was one of malignancy rather than of chronic inflammation. The possibility of lymphogranuloma was suggested, but it was definitely stated that the lesion was not typical.

Late in December, 1927, the patient consulted me again, complaining of digestive disturbance, weakness, and high abdominal pain. He stated that approximately six weeks before his visit, he noticed a swelling, which had increased rapidly in size, in the left part of the abdomen below the edge of the ribs. He also stated that he had lost several pounds in weight during the preceding month.

Examination revealed a large left-sided abdominal mass, distinctly nodular, and plainly splenic in origin. There was no fever, and blood examination, with the exception of a slight anemia of the secondary type, failed to show any abnormality. X-ray examination showed nothing significant, except the shadow of the splenic mass.

Splenectomy was performed on January 5, 1928, in the Jefferson Medical College Hospital. The tumorous spleen was very adherent to the diaphragm and had enlarged so much in the direction of the stomach that it had obliterated the space between the folds of the gastrosplenic omentum. It was, however, removed without any especial difficulty.

The pathologic report submitted by Dr. Baxter L. Crawford was as follows:

"Specimen consists of a spleen which measures 18 by 13 by 8 cm. and weighs 735 Gm. The external surface of the greater part of the spleen is nodular, and the nodules vary in size, and are grayish red in color in sharp contrast to the red color of the splenic tissue. These nodular areas are extremely soft and in some places seem to fluctuate. On section it is seen that the greater part of the splenic pulp has been replaced by nodules of soft gray, homogeneous tissue, which are discrete and sharply defined at the margins. They do not appear to have invaded the splenic capsule. In the larger nodules the tissue is soft, yellowish gray in color, and large areas show necrosis. The small nodules are sharply defined, pearly white in color and soft in consistency.

"Formalin and Zenker's fixations. Routine technique. Histology: Sections show the tumor masses to be composed of cells which vary somewhat in size and shape, but which for the most part are round with rather large, deeply staining nuclei and with a small amount of fibrous tissue stroma. There are numerous small blood vessels in this stroma. The margins of the tumor are sharply circumscribed, and although there is a condensation of the tissue, no definite capsular formation is observed.

"In the adjoining splenic tissue the follicles are numerous, large, and irregular in shape. Many possess large germinal centers. There seems to be a considerable proliferation of the cells of the follicles. The pulp of the spleen appears practically normal.

Fig. 1.—Photomicrograph of a section of the spleen ($\times 50$) showing edge of tumor; the tumor is above, the normal splenic tissue below and to the left. Observe also slight invasion of the spleen along the inferior portion of the section.

"There is no doubt that the lesion in the spleen is a malignant neoplasm, but there is some question as to the origin and type of the cell forming the growth. Because of the multiplicity of the tumors and the marked hyperplasia of the follicles, it is considered to be of lymphoid cell origin, even though in the tumor masses the cells are not identical as to the size and lymphoid type of cell.

"In the larger nodules there is extensive necrosis of the tissue.

"Sections were also stained to demonstrate the reticulum, but nothing unusual was shown in that structure.

"Diagnosis: Lymphosarcoma of the spleen" (Fig. 1).

The patient made a good postoperative recovery and went back to work within a few weeks. He remained in fairly good health until autumn. In November he began to complain of weakness, pain in the thorax, and some difficulty in urinating, and his gait became unsteady. These symptoms increased rapidly, and on December 30 he was read-

Fig 2.—Photomicrograph of a section of the liver ($\times 100$) showing invasion by the tumor; the tumor is above and to the right, the normal liver tissue below and to the left.

Fig. 3.—Photomicrograph of a section of the lung ($\times 100$) showing generalized invasion by the tumor.

mitted to the hospital. At that time he had complete retention of urine and had to be catheterized. By January 15, 1929, there was complete paralysis of the lower extremities and loss of sensation from the soles of the feet to the level of the umbilicus. The paralysis was accompanied by loss of control of both bladder and rectum and was soon followed by the development of gangrenous areas over the sacrum and on the lower extremities. Death occurred on February 18, 1929.

Autopsy was performed the same day by Dr. Crawford. Abridging his report, the following summary may be made: In the liver innumerable grayish nodules of variable

size and consistency were found (Fig. 2). There were also three similar nodules in the left lung (Fig. 3), and one in the cortex of the left kidney (Fig. 4). When the spinal cord was removed, a mass of firm grayish tissue was seen surrounding its lower thoracic and upper lumbar portions (Fig. 5).

Fig. 4.—Photomicrograph of a section of the kidney ($\times 100$) showing invasion by the tumor, especially above and to the left.

Fig. 5.—Photomicrograph of a section of the metastatic growth removed from the spinal cord ($\times 100$) showing its cellular structure.

The histologic structure of nodules removed from all three of these organs, and that of the neoplastic tissue dissected from the spinal cord, was quite similar to the histologic structure of the splenic tumor previously examined. Therefore, a diagnosis of multiple metastatic sarcoma was made.

It is noteworthy that there was no involvement of lymph nodes in any part of the body. A few of the mesenteric and retroperitoneal nodes were slightly enlarged, but microscopic examination showed only hyperplastic changes.

With regard to early symptomatology, it may be stated that malignant tumors of the spleen usually grow rapidly and that they are characterized by local pain, tenderness to pressure, and gastrointestinal disturbances. Very rapid loss of weight has occurred in some cases.

Changes in the blood are inconstant, but Howard,¹ Frank,¹³ and McNee,¹⁵ making independent observations, have called attention to the fact that in lymphosarcoma the picture may simulate that of pernicious anemia. In some cases, however, slight secondary anemia has been the only abnormality detected until late in the course of the disease; and even in some far-advanced cases the changes have been insignificant.

The growth may invade adjacent structures by direct extension and give rise to serious complications. Thus, fatal peritonitis has followed perforation of the colon caused by neoplastic invasion of that structure. The pleura has also been involved by extension of the growth through the diaphragm.

Metastases will affect the clinical picture according to the site in which they occur. For example, in the case of my patient, pressure upon the spinal cord produced a transverse myelitis, which accounted for the paralysis of the lower half of the body, with its accompanying urinary dysfunction and infection, and the development of gangrene over different areas of the paralyzed region.

From the surgeon's standpoint, malignant tumors of the spleen will require differentiation principally from benign tumors, cysts, and abscesses. Infarction without abscess formation should also be taken into consideration. It would seem that the majority of these tumors are nodular, but others, particularly some of the endotheliomas, are smooth. Absence of the normal notches along the anterior border of an enlarged spleen should arouse suspicion of tumor formation.

The prognosis is bad. In the 23 cases that I have collected from the literature, splenectomy was performed in 15. In two other instances the condition was found to be inoperable when the abdomen of the patient was opened. One of the patients died a few hours after operation; the other lived for four and one-half months. Of the nine who survived splenectomy, five are known to have died of metastases at periods varying from a few weeks to eighteen months after their discharge from the hospital. In three of the five remaining cases only a few months had elapsed between operation and publication of the case reports, so that a definite statement as to the ultimate result could not be made. The fourth patient, who had remained free from recurrence for nearly four years, developed a mass in the left flank, but it was questionable whether the lesion was metastatic sarcoma or primary carcinoma of the colon. The patient refused operation. The fifth patient was well five and one-half years after operation. The case was one of hemangio-endothelioma. Death occurred in the six cases in which operation was not undertaken.

Some pathologists believe lymphosarcoma to be part of a generalized malignant process, which will attack other structures in the reticulo-endothelial sys-

tem simultaneously with, or subsequently to, its beginning in the spleen. Furthermore, endothelial tumors have been followed by metastasis in a very short time after their removal. In a few cases, however, including both types of tumor, there has not been any reappearance of the disease for several years after extirpation of the spleen; consequently, splenectomy is advisable, provided that there are no signs of involvement of other organs when the patient first came under observation.

I am greatly indebted to Dr. Baxter L. Crawford and Dr. Carl J. Bucher, of the Pathological Department of the Jefferson Medical College and Hospital, for their cooperation in the study of the case herein reported.

A COMPARISON OF THE HINTON, KAHN, KLINE, AND MAZZINI TESTS FOR SYPHILIS*

EDWARD L. BREAZEALE, B.S.A., ROBERT A. GREENE, PH.D., AND
HARRY B. HARDING, B.S., TUCSON, ARIZ.

IT HAS been the practice of this laboratory to perform the Hinton, Kahn standard, and Kline diagnostic tests on all blood specimens submitted for serologic examinations. The specificity and sensitivity of these tests have been established by many comparative studies and by several nationwide evaluation studies.

Mazzini¹ has recently described a slide test for syphilis which is claimed to be high in sensitivity and specificity, and which has many desirable features from the standpoint of performance. Giordano² and his co-workers have confirmed Mazzini's findings.

Since it appeared that the Mazzini test might be a valuable addition to our present procedure, this investigation was made to determine what agreement we might secure with the four tests.

PROCEDURE

When specimens were received, the sera were separated and inactivated in an electrically controlled water bath at 56° C. for thirty minutes. The Hinton, Kahn standard, Kline diagnostic, and Mazzini tests were employed in the examination of each specimen. The Hinton and Kahn antigens were prepared in this laboratory and were checked against "standard" antigens for sensitivity and specificity; the Kline antigen was purchased from LaMotte and the Mazzini antigen was furnished by Mr. L. Y. Mazzini. In the performance of the tests, the technique of the originators was strictly followed. The results are given in Tables I and II.

DISCUSSION

Tables I and II show a complete agreement of all four tests in 2,818 sera (93.93 per cent), and a relative agreement in 2,858 (95.26 per cent). In an earlier study³ we reported that the Eagle, Ide, Kahn, Kline, and Laughlen tests agreed in 98.5 to 99.5 per cent of the sera examined. Lack of agreement was noted chiefly in sera which gave doubtful or weakly positive reactions.

In this study agreement was slightly lower than in our comparison of 1937. Lack of agreement usually occurred in sera which gave doubtful or weakly positive reactions. In several cases, however, one or more of the tests gave strongly positive reactions, while the others gave negative or doubtful ones.

*From the Arizona State Laboratory, Tucson.
Received for publication, December 4, 1939.

TABLE I
COMPLETE AGREEMENT OF HINTON, KAHN, KLINE, AND MAZZINI TESTS

	NUMBER OF SPECIMENS	PER CENT
All negative	2,184	72.80
All doubtful	17	0.56
All weakly positive	309	10.30
All strongly positive	308	10.27
Total	2,818	93.93
Results not agreeing	182	6.07
Complete total	3,000	100.00

TABLE II
RELATIVE AGREEMENT OF TESTS

	NUMBER OF SPECIMENS	PER CENT
All negative	2,184	72.80
All showing partial (\pm) or complete (+) reactions	674	22.46
Total	2,858	95.26
Results not agreeing	142	4.74
Complete total	3,000	100.00

We feel that this lack of agreement is due to two factors: (1) A larger percentage of specimens from treated, latent, and congenital cases. In 1937 specimens were chiefly from clinically diagnosed syphilitics or from presumably negative groups. With the expansion of the Venereal Disease Control Program, an increasing number of specimens come from known treated or suspected congenital cases. Mazzini¹ and Maltaner⁵ have shown that in such groups the results of various tests may vary widely. A comparison with the 1937 study supports this idea.

	1937 %	1939 %
All tests negative	82.3	72.80
All tests doubtful	1.7	0.56
All tests positive	14.3	20.57
Results not agreeing	1.7	6.07

(2) With the expansion of the Venereal Disease Control Program, more specimens are submitted for the laboratory diagnosis of syphilis and a large percentage come from cases of chronic, undiagnosed illnesses. This results in an increase of nonspecific, or "false positive," laboratory tests.

Much has been written about the specificity of the various laboratory tests for syphilis. Evaluation studies have shown that the more common tests will give between 99 and 100 per cent negative reactions among presumably non-syphilitics, and that they will detect approximately 80 to 90 per cent of known syphilitics (all types, latent, treated, etc.). In secondary syphilis the tests will detect almost 100 per cent of the cases. In such groups, our results have been well within the limits of sensitivity and specificity recommended by the United States Public Health Service.

TABLE III

DISTRIBUTION OF REACTIONS IN 182 SPECIMENS WHERE RESULTS WERE NOT IN COMPLETE AGREEMENT

(\pm and 1+ reactions called doubtful; 2+ and stronger called positive; Hinton test reported as --, \pm , or +; other tests as --, \pm , 1+, 2+, 3+, 4+)

TABLE IV

DISTRIBUTION OF REACTIONS IN 3,000 SPECIMENS

	HINTON	KAHN	KLINE	MAZZINI
Negative	2,258	2,250	2,256	2,228
Doubtful or weakly positive	369	415	403	394
Positive	373	335	341	378
Total	3,000	3,000	3,000	3,000

Many diseases other than syphilis have been credited with the responsibility of nonspecific serologic tests for syphilis. Among these are yaws, tuberculosis, malaria, leprosy, infectious mononucleosis and numerous other diseases (particularly high febrile conditions). Recently, Krag and Lonberg⁴ have stated "affections of the respiratory passages are the most frequent cause of nonspecific reactions."

The question of nonspecific reactions is complicated by the fact that in some cases it is not possible to eliminate syphilis definitely, and that the sera of nonsyphilitics may contain "reagin" at times. Judging from our experience, nonspecific reactions occur, and chiefly among presumably nonsyphilitic individuals who are suffering from chronic, undiagnosed illnesses. At first, these were dismissed as laboratory errors, but after an extensive series of checks with other laboratories, we have come to regard them as nonspecific.

Tables V and VI give in detail some of the reactions given by the tests in known syphilitics and in presumably nonsyphilitics. These cases, where there was a lack of agreement, are the only ones included, except for the presumably "nonspecific" reactions. The diagnosis and comments are those furnished by the physicians who submitted the specimens.

In addition to the results given in the preceding tables, the Kline and Mazzini tests were employed as "screening tests" in a series of 1,042 specimens from a group of college students. The results are indicated in Table VII. Complete agreement in this series was 99.51 per cent; relative agreement was 99.80 per cent.

The Kahn and Hinton tests were applied to the ten specimens which gave some reaction to the Kline or Mazzini tests. The results are given in Table VIII.

These specimens were all rechecked within a period of from seven to fourteen days. The following sera gave negative Hinton, Kahn, Kline, and Mazzini reactions upon the second test: 4, 5, 6, 7, 9, and 10. The others gave the reactions shown in Table IX.

At the time this article was written, further investigations had not been completed. With the exception of specimen No. 8, there is good reason to believe that the reactions by sera Nos. 1, 2, and 3 are nonspecific.

Tables III and IV show that the Kline, Kahn, and Hinton tests gave approximately the same number of negative reactions, and that the Mazzini test gave fewer negative and more positive reactions. This is to be expected, however, since the sensitivity of the Mazzini test is of the same order as the Kline

exclusion test. Table IV shows a good relative agreement between the Kline, Kahn, and Hinton tests.

Table V confirms the results of Mazzini¹ and Giordano² as to the sensitivity of the Mazzini test, and also shows, as have Mazzini¹ and Maltaner,⁵ that many persons known to have syphilis may give positive reactions with one or more tests and negative reactions with others. It is interesting to note that in such cases a less sensitive test may often give a positive reaction, while a more sensitive test may be negative.

Table V also shows the advantage of the use of a system of multiple tests, as suggested by Pierce.⁶ The use of such a system has been criticized by several authors on the grounds that conflicting results are of little value to the physician. After all, he is the final judge of the laboratory report and must interpret such results in the light of clinical evidence. Although Table VI shows few cases which are presumably "false positive," or nonspecific reactions, there are many instances where clinically diagnosed cases of syphilis give similar conflicting results with the various tests. From this experience, we feel that the use of a multiple test system is warranted, and that conflicting results from several tests should not necessarily be regarded as a limitation of any particular laboratory test.

It is our opinion that as the Venereal Disease Program continues to expand, there will be an increase in the type of results given in Table V, and that an appreciation of this fact will lead to a better understanding between the laboratory and the clinician.

TABLE IX

SERUM	HINTON	KAHN	KLINE	MAZZINI	WASSERMANN
1	--	1+	2+	3+	--
2	±	--	1+	3+	--
3	--	1+	--	2+	--
8	+	4+	4+	4+	4+

SUMMARY

These results confirm the findings of Mazzini and Giordano as to the specificity and sensitivity of the Mazzini test.

Since the Mazzini test is more sensitive than the Kline and Kahn diagnostic tests and the Hinton test, it gave a lower incidence of negative reactions and a higher incidence of positive findings.

The Kline, Kahn, Hinton and Mazzini tests gave a relative agreement of approximately 95.26 per cent, and an absolute agreement of 93.93 per cent. In an additional series of 1,042 specimens from college students, the Kline and Mazzini tests gave a relative agreement of 99.8 per cent and a complete agreement of 99.51 per cent.

The occurrence of nonspecific ("false positive") reactions is mentioned.

The occurrence of conflicting results of various tests in clinically diagnosed cases of syphilis is discussed.

The results, in our opinion, justify the use of a multiple test system.

In our opinion the Mazzini test is an excellent test for the laboratory diagnosis of syphilis.

We gratefully acknowledge the assistance of Mr. L. Y. Mazzini, who supplied the antigen for the Mazzini test, and the physicians who assisted us by giving case histories.

BACTERIOLOGIC DIAGNOSIS IN GONORRHEA OF THE MALE*

AXEL GRONAU, M.D., ST. LOUIS, MO.

A BACTERIOLOGIC study of 221 patients with genitourinary infections is presented, and a comparison is made between the efficiency of the smear method and the cultural method as a means of diagnosis. These patients were repeatedly examined over a period of eight months. A total of 819 bacteriologic examinations, each examination consisting of smear and culture, were made on the 221 patients, of whom 160 were definitely proved to have gonorrhea by bacteriologic examination as well as by clinical evidence. Sixty-one patients were assumed to have some genitourinary infection other than gonorrhea and, while the actual cause of the infection was not established, at no time were gonococci found either by smear or culture.

METHODS

Smears: Material for smears consisted of urethral discharge, sediment of urine, and prostatic secretion, obtained after massage. The material was collected on a swab or loop and distributed with rolling or streaking motions over the glass slide.

Staining procedure: Hucker's staining method, which we modified by employing mercuric chloride as a fixative and acetone as a decolorizing agent, was used. It was found that mercuric chloride in 1 per cent solution applied for one minute to the smears would preserve the details of the cells especially well.

Cultural methods: In attempting to grow gonococcus the work of McLeod and co-workers,¹ Leahy and Carpenter,² and Carpenter,³ was taken into account. The specimens for culture, which were the same as those for the smears, were collected on a sterile swab. The swab was then placed into 1.5 c.c. of broth, and the material on the swab was suspended in the broth. For technical reasons it

*From the Department of Bacteriology and Immunology, Washington University School of Medicine, St. Louis.

This investigation was assisted by a special allotment of funds to the Washington University School of Medicine by the United States Public Health Service.

Received for publication, December 8, 1939.

was not possible to plate out the material at once, but the broth suspensions were exposed to room temperature for one and one-half to two hours before being cultured. Only in a very few cases was the glans penis cleaned, since in most cases there was not sufficient time to do it. By proper manipulations a large number of contaminations could be avoided, so that the contaminants growing on the plates would not interfere with the growth of the gonococcus. Cultures were taken only after the patients had stopped treatment for four to five days.

A 5 per cent rabbit blood chocolate agar was used, with hormone broth as a base. The blood was added to the agar, kept at a temperature of between 70° and 85° C. The final agar concentration in the medium was 1.7 per cent. The chocolate agar plates were kept in the icebox. They were not used when older than three days, since it was found that only a high amount of moisture would guarantee satisfactory growth.

Some of the broth suspension was placed on the medium by means of the swab and was then streaked out with the loop. Incubation was effected at 36° C. for about forty hours under 10 per cent carbon dioxide tension.

After forty hours' incubation the plates were inspected, and colorless, opaque colonies with irregular edges were touched with a drop of a 1 per cent watery solution of para-amino-dimethyl-aniline-monohydrochloride (Eastman Kodak), prepared fresh as soon as the solution showed some precipitate. This solution was kept in the refrigerator. If no suspicious colonies were found by mere inspection, the entire plate was flooded with the solution for a moment, and then the excess solution was poured off. Gonococcus colonies gave a typical oxidase reaction; the colonies turned pink in about ten seconds, and in the course of some minutes gradually became black. Gram-stained preparations of colonies giving a typical oxidase reaction were invariably found to consist of gram-negative diplococci. The oxidase reaction does not interfere with the characteristic staining properties of the gonococcus.

Besides gonococcus, other organisms will give the oxidase reaction. All or most of the members of the *Neisseria* group will give this reaction. With the exception of the meningococcus, whose colony cannot be very well differentiated from the gonococcus colony on a chocolate agar medium, and which also gives an oxidase reaction very similar to that of the gonococcus, the other members of the *Neisseria* group can be easily recognized from the gonococcus by their growth characteristics; they also give an oxidase reaction that is somewhat different from that of the gonococcus.

While diphtheroids do not generally give the oxidase reaction, occasionally colonies of gram-positive rods, which we assumed to be diphtheroids, were found to change their color when the oxidase stain was applied to them. However, besides being gram-positive, they could be differentiated easily from the gonococcus, giving an absolutely atypical reaction, and turning to a chalky, grayish black after fifteen to twenty minutes. When these colonies were pushed aside with the loop, the underlying medium would generally not have taken up any of the dark color, whereas the medium under gonococcus colonies, after they gave the oxidase reaction, would also be stained black. Furthermore, if a gonococcus

colony is pushed aside, a distinctly positive oxidase reaction may be obtained by applying the oxidase stain to that place of the medium where the gonococcus colony had been before. This we found did not occur with diplotheroids which gave the atypical reaction just mentioned.

In 41 cases where colonies on the basis of their morphologic character and on their property of giving a typical oxidase reaction were thought to be gonococci, the suspected colonies were isolated in pure culture and fermentation tests on an ascitic fluid agar sugar medium, as well as sodium hydroxide solubility tests, were done. In every case the tests gave the reactions characteristic of gonococcus. Besides, as a further control, all the 41 cultures were transferred to a 7 per cent horse blood agar plate and incubated at 23° to 24° C. for forty-eight hours, but without the adjustment of carbon dioxide tension. With the exception of two strains the organisms failed to grow.

On the basis of these preliminary findings in a subsequent routine procedure, all colonies, which resembled gonococcus colonies by inspection, by typical oxidase reaction, and showed gram-negative diplococci were considered to be gonococci without using fermentation tests as a means of further identification, provided these organisms were derived from the genitourinary tract of a male with a typical history indicating gonorrheal infection.

We are aware of the possibility that this method might fail to differentiate meningococci from gonococci; but in view of the rarity of meningococcal infection of the male genitourinary tract, we thought it justifiable to give out a report as positive, without going through the very time-consuming procedure of first growing the organisms in pure culture and then running fermentation tests, providing our previously stated criteria of gonococcus were satisfied.

METHOD OF REPORTING

Cultures: A culture was reported as "+" when gonococcus colonies were found, and as "0" when no such colonies were found.

Smears: A smear was reported as "+" when intracellular gram-negative diplococci resembling gonococci were found; as "±" when gram-negative diplococci resembling gonococci were found extracellularly; as "0" when such organisms were found neither intracellularly nor extracellularly.

RESULTS

A total of 819 examinations, employing both culture and smear methods simultaneously, were carried out on 221 patients.

Stain and culture agreed in 722 instances, or in 88.16 per cent.

Stain	+	} 137 = 16.73%	Stain	0	} 585 = 71.43%
Culture	+		Culture	0	

Stain and culture disagreed in 97 instances, or in 11.84 per cent.

Stain	0	} 30 = 3.66%	Stain	+	} 5 = 0.61%
Culture	+		Culture	0	
Stain	±	} 13 = 1.59%	Stain	±	} 49 = 5.98%
Culture	+		Culture	0	

The presence of gonococcus was revealed by either smear or culture method, or both methods, in a total of 185 instances of the 819 examinations. The relative efficiency of the smear or culture method for detection of the presence of gonococcus may be calculated from the following figures, taking the number 185 as 100 per cent deficiency:

Stain	+	} 137 = 74.05%	Stain	0	} 30 = 16.22%	} Difference 13.52%
Culture	+		Culture	+		
Stain	±	} 13 = 7.03%	Stain	+	} 5 = 2.70%	
Culture	+		Culture	0		

Thus, we see that there is a decided superiority of 13.52 per cent of the cultural method over the smear method. In other words, in 13.52 per cent the culture method detected gonococci, when the smear method failed to do so. In addition, in 7.03 per cent the culture method definitely revealed gonococci when the smear method was doubtful.

Three of the 5 stain + culture 0 findings occurred during the first two months of our investigation, when we were not as familiar with the growth conditions of gonococcus as we were later; and it is believed that in these instances the failure of the gonococcus to grow might have been due, perhaps, to too long storage of the medium with a subsequent loss of moisture.

As we have already stated, the report "±" referring to the smear signified "gram-negative diplococci, resembling gonococci, situated extracellularly." Thus, in reporting a smear as "±," it was necessary in the first place to decide whether the extracellular organisms were gram-negative, then whether they were diplococci, and finally whether they resembled the gonococci. While it is often an easy matter to arrive at the report "±," there is a considerable number of smears where the decision is difficult, and the personal equation enters as in no other phase of the work. In many smears where the culture exhibited staphylococci and diphtheroids only, the smear showed besides gram-positive cocci, cocci that were not definitely gram-positive or gram-negative, associated at times in diplococcus formation. The decision whether these organisms are also staphylococci, which just did not stain as well as the others, or whether they should be regarded as being possibly gonococci, is entirely a matter of personal judgment, and even the same observer looking at a given smear today may come to a different decision tomorrow.

Taking the total of 819 smears and cultures as 100 per cent, we see that in 62 instances (7.57 per cent) the smear was reported as "±." In 13 of these instances (1.59 per cent) the diagnosis was settled by the simultaneous positive culture. In 49 instances (5.98 per cent) the culture proved to be negative. These 49 doubtful "±" smears occurred on 43 patients, 11 of whom were regarded as being affected with some genitourinary infection other than gonorrhea, and on whom at no time a definite positive finding had been obtained. The other 32 patients had clinical gonorrhea confirmed on admission by smear and culture, but who at a later date exhibited a "±" smear along with a negative culture.

It was at first difficult for us to correlate the " \pm " findings of the smears with the simultaneous negative findings of the cultures, since it may have been possible that the suspicious organisms found in the smear were gonococci, which just would not grow under the conditions to which they were subjected by our methods. However, when more data were available, it was felt that in judging whether the organisms responsible for the " \pm " report of a smear were gonococci or not, the deciding factor should be the culture, in the sense that if no gonococci were found on the culture, the suspected organisms in the smear should not be assumed to be gonococci. This assumption seemed to be justified by the following reasoning: It was very unlikely that in the case of a doubtful " \pm " smear and a negative culture we would deal with a strain of gonococcus that would not grow under our methods, since a positive culture was obtained in every case where these patients showed a definitely positive smear on admission.

We further undertook a follow-up study of the patients who exhibited a stain \pm culture 0 report, with the idea that if the suspicious organisms in the " \pm " smear were gonococci, the symptoms of the patients might again exacerbate and culture and stain become positive. The findings of this study are as follows:

In the large majority of patients there were several reports of negative smears and cultures preceding the " \pm " smear. Five patients were found unsatisfactory for any analysis, either because they did not return or because they allowed themselves to be exposed during the time of observation. Twenty-six patients, of whom 12 have been definitely dismissed as cured, showed only stain 0 culture 0 findings after the stain \pm culture 0 report. Fourteen of the 26 patients have not been dismissed at this time, and show repeatedly a stain 0 culture 0 report after the stain \pm culture 0 report. Most of these have been put through provocative measures as massage, introduction of sound, permission of alcohol and coitus, without either culture or stain becoming positive. Three of the 14 patients not yet dismissed had, we believe, reinfections. For a period of two and one-half to three months after the stain \pm culture 0 report, during which these patients were examined repeatedly, no positive or " \pm " findings occurred. These patients were finally permitted to stay away for twenty-eight days; they returned with an acute discharge. One of the patients admitted exposure without prophylaxis.

Only in one of the 32 patients was there a stain 0 culture + finding after the stain \pm culture 0 report.

We admit that this method of analyzing the significance of a " \pm " finding on the smear by follow-up studies is very much open to criticism. However, we thought that some additional information might thus be gained.

Reviewing this analysis, we see that in only 5 instances of 819 bacteriologic examinations, an incidence of 0.61 per cent, where the stain was positive and the simultaneous culture was negative, did the stain detect something important that the culture did not reveal.

CONCLUSIONS

1. A total of 819 bacteriologic examinations, employing simultaneously culture and smear methods as a means of diagnosis, were carried out on 221 patients.

2. The culture and smear methods agreed in 88.16 per cent and disagreed in 11.84 per cent of the cases, taking the 819 examinations as 100 per cent.

3. In 185 instances the presence of gonococci was revealed by either smear or culture, or both methods. Taking the number 185 as 100 per cent efficiency in detecting gonococci, we find that the culture was able to detect gonococci in 13.52 per cent, when the smear definitely failed to do so. In addition, in 7.03 per cent, the culture definitely revealed gonococci, when the smear was doubtful.

EXPERIMENTAL THROMBOCYTOPENIC PURPURA IN THE GUINEA PIG*

MAURICE E. LEONARD, M.D., AND ERNEST H. FALCONER, M.D.
SAN FRANCISCO, CALIF.

SINCE Werlhof first gave an accurate clinical description of essential thrombocytopenic purpura, it has been known that a marked reduction of the circulating blood platelets is a characteristic feature of the condition. However, many students of this disease believe that other factors must be in operation to produce the clinical picture, and it has been assumed that some change in the capillaries must be the ultimate cause of the leakage of blood through them.

This study was planned as an attempt to estimate the relative roles played by the blood platelets and the capillaries. Our approach to the problem was as follows: (1) by producing thrombocytopenia, and (2) by producing increased capillary fragility.

Experimental Production of Thrombocytopenia.—Numerous investigators have studied the effects of various substances upon blood platelets.²⁻²¹

Duke² was apparently the first in this country to attempt to produce thrombocytopenic purpura, and for this purpose he used benzol. Ledingham³

*From the Department of Medicine, University of California Medical School, San Francisco. Supported by a grant from the Christine Breon Fund.
Received for publication, December 11, 1939.

in 1914 reported the results of an experiment in which thrombocytopenic purpura was produced in guinea pigs following injections of an antiplatelet serum which was capable of selectively destroying circulating platelets. Ledingham and Bedson,⁴ and Bedson,^{15, 16, 20} after studying the properties of this serum, concluded that it contained a specific antibody capable of lysing and agglutinating blood platelets *in vivo*, without affecting the other formed elements of the blood. Tocantins^{7, 8} studied the thrombocytopenic purpura produced in dogs with an antiplatelet serum, and more recently Troland and Lee²¹ produced thrombocytopenic purpura in rabbits with an extract obtained from the spleen of patients with thrombocytopenic purpura.

Experimental Production of Increased Capillary Fragility.—Our problem was to find a method for producing capillary damage that could be maintained over long periods, that would in itself not cause purpura, and that could be controlled to some extent. We employed vitamin C deficiency as the method that best fulfilled these conditions. Our attempt was to produce vitamin C depletion without reaching the point of definite clinical scurvy. Vitamin C has been regarded by many as an important factor in the hemorrhagic diseases, from both the etiologic and therapeutic standpoints.²²⁻¹² In recent years capillary fragility has been employed extensively as an indirect measure of the degree of vitamin C storage.²³⁻¹¹

METHODS

An antiplatelet serum was prepared in the following manner: One hundred to 130 c.c. of blood were obtained from guinea pigs by cardiac puncture. The blood was collected in an equal volume of 3.8 per cent sodium citrate in normal salt solution. The platelets were extracted from the solution by fractional centrifugalization, and after being suspended in 10 c.c. physiologic salt solution, were injected intravenously into a rabbit. This procedure was carried out at intervals of five to seven days, until the rabbit had received from three to six injections. At the end of this time the blood was withdrawn from the rabbit by cardiac puncture, stored in the refrigerator overnight, and the serum separated out and collected in sterile bottles. Because it was found that the antiplatelet serum lost potency in a relatively short time, all subsequent sera were lyophilized according to the technique of Flosdorff and Mudd.⁴²

Hemoglobin determinations were made with standardized Sahli instruments in which 100 per cent equal 13.8 Gm. of hemoglobin per 100 c.c. of blood. Erythrocyte and leucocyte counts were made with standard pipettes and a Neubauer counting chamber, all instruments being standardized by the United States Bureau of Standards. Platelets were counted directly in the counting chamber after diluting 1:100 in the standard red blood cell pipettes with Reese and Ecker fluid.¹ A period of ten minutes was allowed to elapse from the time the fluid was placed in the counting chamber until the count was begun.

Capillary resistance was measured by the Dalldorf technique,³⁷ employing the da Silva-Mello instrument. We used the skin over the lower portion of the abdomen, which had been carefully shaved at least twenty-four hours before the readings were taken.

Twelve young guinea pigs, weighing between 200 and 300 Gm., were chosen. Six were segregated and placed upon a diet consisting of baked skimmed milk, 30.0 per cent; butter fat, 10.0 per cent; rolled oats and bran, 56.0 per cent; sodium chloride, 0.5 per cent; Osborne and Mendel salt mixture, 1.5 per cent; dried yeast, 1.0 per cent; and cod-liver oil, 1.0 per cent. This group was designated as the scurvy (S) group.

Six animals were placed upon a diet consisting of barley, alfalfa, salt, and greens (lettuce and cabbage) supplemented with 2 c.c. of orange juice daily. This was designated as the control (C) group.

EXPERIMENTAL

Effect of Diet on the Weight, Blood Picture, and Capillary Fragility of Guinea Pigs.—The results are shown in Table I. There was a definite influence of vitamin C deficiency on growth. These animals were at the age when rapid growth is expected, and, although the vitamin C deficiency animals showed some increase in weight, it was neither as uniform nor as great as that shown by the animals receiving vitamin C.

The values for hemoglobin, erythrocytes, leucocytes, and blood platelets were statistically similar in the two groups, whereas the capillary fragility showed considerable difference. The vitamin C deficiency animals showed a distinctly greater capillary fragility when measured by the Dalldorf method. The effect of the deficiency was more marked on the capillaries than on the formed elements of the blood.

Effect of Antiplatelet Serum on Guinea Pigs With Vitamin C Deficiency and With High Vitamin C Diets.—Six guinea pigs, three with vitamin C deficiency and high capillary fragility and three on diets high in vitamin C and with low capillary fragility, were chosen. The animals were given antiplatelet serum intraperitoneally. Four received 0.2 c.c. and two of the control group received 0.3 c.c. The results (Table II and Fig. 1) were strikingly similar. Before the injection of antiplatelet serum, the average platelet count was 600,000 per cubic millimeter in the vitamin C deficient animals and 710,000 per cubic millimeter in the control animals. Twenty-four hours after the injection the platelet count had fallen to 70,000 and 40,000 per cubic millimeter, respectively. This was

associated with the appearance of purpura, increased bleeding time, and poor clot retraction. The clot was so soft and friable that twenty-four hours after the previous skin puncture, the clot could be wiped away and persistent oozing would follow. Forty-eight hours after the injection, the platelets began to increase again, reaching by the fifth day 380,000 per cubic millimeter in the vitamin C deficient animals and 400,000 per cubic millimeter in the controls. A second injection of the serum (0.2 c.c.) again produced a rapid drop in platelets; this was followed by the appearance of purpura. The platelet drop was very marked within six-hours after the injection, but was maximal at twenty-four hours.

Fig. 1.

Two of the animals (control) died, one forty-eight hours and one fifty-two hours after the injection. Necropsy showed bleeding into the internal organs and serous membranes. Death was apparently due to exsanguination. In all surviving animals the purpuric lesions disappeared in from three to five days.

Effect of Normal Rabbit Serum on Guinea Pigs Deficient in Vitamin C.—In order to determine whether normal rabbit serum had any effect upon blood platelets, injections ranging in dosage from 0.2 to 1.0 c.c. were given to five animals with vitamin C deficiency. The data are shown in Table III. There was no significant variation in the platelet levels and no evidence of a bleeding tendency. This definitely indicates that (1) the platelet-destroying property of the antiserum is not inherent in the rabbit serum; (2) normal rabbit serum will not alter the capillary permeability sufficiently to cause bleeding.

Effect of Increasing Doses of Antiplatelet and Normal Rabbit Serum on Vitamin C Deficient Guinea Pigs.—Two vitamin C deficient animals were given injections of antiplatelet serum in increasing doses, ranging from 0.05 c.c. to 0.3 c.c. One animal was given normal rabbit serum in the same manner. (Results are shown in Tables IV and V and Fig. 2.) The smallest dose (0.05 c.c.)

of antiplatelet serum was followed by a drop in the platelet level (from 570,000 to 280,000 per cubic millimeter), but this was not regarded as being significant. Following an injection of 0.1 c.c., the platelet level dropped to 75,000 per cubic millimeter. Larger doses produced no further significant decrease in the platelet level, but a dose of 0.2 c.c. was required to produce purpura and increased bleeding time.

Following injections of serum from a normal rabbit, there was no significant change in the level of blood platelets. There was variation, ranging from 368,000 to 650,000 per cubic millimeter (Table V and Fig. 2), but this was within the probability of normal variation, as established by the statistical constants.

Apparently the maximum effect of the antiplatelet serum cannot be exceeded by increasing the dosage, but is inherent in the potency of the serum.

Effect of Antiplatelet Serum Diluted With Normal Rabbit Serum.—We attempted to find whether dilution would result in loss of potency and whether the admixture of normal serum would result in changes in the antiplatelet properties of the antiplatelet serum. Four normal guinea pigs were given injections

of mixtures of antiplatelet serum and normal rabbit serum. The total volume of serum injected was 1 c.c., of which the antiplatelet portion ranged from 0.1 to 0.7 c.c. There was no difference between the response to the mixed serum and that which had been observed using the straight antiplatelet serum (Table VI). When the proportion of antiplatelet serum reached 0.2 c.c., there followed within twenty-four hours a marked platelet drop (from 250,000 to 60,000 per cubic millimeter) associated with hemorrhagic phenomena.

Fig. 2.

DISCUSSION

It is difficult to draw definite conclusions when dealing with experiments that present uncontrollable variables. However, we feel that certain facts appeared consistently enough to warrant attention. The most striking and consistent factor was the apparent relationship between the blood platelet level and the bleeding time. Generally, when the platelet level fell below 70,000 per cubic millimeter, a condition was produced similar to that commonly seen in human thrombocytopenic purpura, i.e., prolonged bleeding time, normal clotting time, poor clot retraction, and bleeding into the skin, mucous membranes, and internal organs. This was not always the case, as instances were observed when a low platelet count was not associated with purpuric manifestations. The rapidity of the fall in the platelet level, as well as the absolute number of circulating platelets, appeared to be important factors. This may explain why very small doses of serum, although capable of producing thrombopenia, were unable to cause bleeding.

This study was predicated upon the assumption that a capillary lesion, in addition to a platelet deficiency, is necessary for purpura to occur. The presence of a capillary lesion was assumed when an increased capillary fragility was shown by the Dalldorf technique for estimating capillary fragility. In evaluating the part played by the capillary lesion in thrombocytopenic purpura, we considered that the capillary bed in vitamin C deficiency might be very per-

meable and allow capillary hemorrhages to occur, with slight reductions in the platelet level, i.e., a level above that necessary to cause purpura in a normal animal. As has been found in these experiments, such a premise was not warranted. Unfortunately, we have no means of showing mathematical correlation between vitamin C deficiency, capillary fragility, and purpura, but so far as our experiments are concerned, there appears to be none.

This does not mean that vitamin C is not concerned with capillary fragility, but it does indicate that the type of capillary change which we assume to be present in thrombocytopenic purpura is of a different order. Treatment of this disorder with vitamin C does not appear to have a rational basis.

Our findings fail to verify our original conception that an anatomic capillary lesion must be present before hemorrhage can occur. It is more likely that the passage of blood through the walls of the vessels is determined by the functional state of the capillaries, i.e., their degree of dilatation. This vasodilatation, when associated with a considerable platelet deficiency, may be the mechanism by which hemorrhage is produced. Capillary dilatation may be initiated by the rapid disintegration of platelets liberating some substances possibly of a histamine-like nature. We have no proof of this hypothesis, but experiments are under way to investigate the mechanism of capillary dilatation.

SUMMARY

An antiplatelet serum has been produced that is capable of selectively destroying blood platelets and causing purpura. The production of purpura is apparently related to the quantitative reduction in the number of circulating platelets and to the rapidity of the fall in the platelet level.

The effect of the serum on animals with anatomically intact capillaries and on animals with capillary lesions (vitamin C deficiency) is the same. This suggests that the capillary factor is functional rather than anatomic and could be more profitably studied by physiologic means. The hypothesis is advanced that capillary dilatation in addition to a platelet deficiency is necessary before hemorrhage can occur.

Vitamin C does not protect guinea pigs against experimentally produced thrombocytopenic purpura.

THE DEPRESSOR EFFECT OF POTASSIUM SULFOCYANATE BEFORE AND AFTER BILATERAL SPLANCHNICOTOMY IN NORMAL AND HYPERTENSIVE DOGS*

LOYAL DAVIS, M.D., AND M. HERBERT BARKER, M.D., CHICAGO, ILL.

IN ANOTHER paper we¹ have reported our experimental and clinical experiences with the administration of potassium sulfoeyanate to patients with essential hypertension and to dogs with hypertension produced by the Goldblatt ischemic method.

It has been shown that a certain number of patients with essential hypertension react favorably to the administration of potassium sulfoeyanate if the individual dosage is carefully controlled by blood cyanate level determinations. Accompanying the fall in the systolic and diastolic blood pressures, there is a decrease in the blood serum proteins; the blood cholesterol falls; the sedimentation rate increases markedly and the hematocrit reading decreases. These favorable reactions to the cyanates in patients have been confirmed in the experimental laboratory by administering the drug to normal and hypertensive dogs.

In another group of patients with essential hypertension, the response to the cyanates may be poor, and attempts to obtain a more favorable effect by increasing the level of the cyanates in the blood are followed by symptoms of cyanate toxicity which require that the administration of the drug be stopped.

We have also reported that after removal of the splanchnic nerves supradiaphragmatically in those patients with essential hypertension who have responded poorly to cyanate therapy, a certain number definitely react more favorably to the drug. The blood pressure levels, both systolic and diastolic, the blood cholesterol, serum proteins, hematocrit, and sedimentation rate accurately reflect this conversion to a satisfactory response.

As yet no one has been able to explain satisfactorily the effect of potassium sulfoeyanate in the treatment of essential hypertension. Claude Bernard and other earlier investigators believed that sulfoeyanate exerted its effect because it was a direct muscle poison and abolished muscular activity, a theory long since disproved. Westphal and Blum² suggested on purely theoretical grounds that cholesterol, as well as protein cleavage products, decreased the permeability of the cell membrane of the smooth muscles of the arterioles. Such a condition they believed, would favor an excessive retention of pressor substances in the cell normally present for the maintenance of tonus, and thus persistent arterial hypertonus would result. They further stated that the salt action of the cyanation might act upon the cholesterol at the cell membrane to produce an increase

*From the Divisions of Surgery and Medicine, Northwestern University Medical School, Chicago.

Received for publication, December 15, 1939.

in the permeability of the arterial muscle cells, thus allowing an escape of the retained pressor substance which would result in a lowering of arterial tension. Although this explanation has never been accepted fully, some support is afforded by Gellhorn³ who observed that weak solutions of cyanate ion permeated the isolated striated muscle of a frog so slowly that no contraction occurred, but that when that same muscle containing cyanate ion was transferred to a cyanate-free solution, withdrawal of the ion was so rapid that actual contracture was produced. Thus he concluded that the ion had definitely increased the permeability of the muscle cell membrane.

Fig. 1.—Blood pressure response of a normal dog (weight, 17.2 kg.) to an intravenous injection of 0.25 Gm. of potassium sulfoeyanate.

In an effort to learn something of the method of action of potassium sulfoeyanate, a series of acute experiments were carried out upon six dogs with experimental ischemic hypertension, twelve normal dogs, and four normal dogs to which potassium sulfoeyanate had been administered over a sufficiently long period of time to establish a high blood cyanate level. In all of the hypertensive animals, in seven of the normal dogs, and in all of the normal dogs with blood cyanate levels, blood pressure tracings were taken before and after bilateral removal of 3 to 4 inches of the thoracic sympathetic trunks and ganglia above the diaphragm and section of the greater and lesser splanchnic nerves. Blood pressure tracings were made with a cannula in the carotid artery, and injections of potassium sulfoeyanate were made into the femoral vein. A tracheal cannula connected with an oxygen tank and an automatic respirator was used in each experiment and successfully combated the respiratory difficulties which attend opening the thoracic cavity bilaterally. In some of the early experiments a record of the outflow from the coronary artery was made.

The results of these acute experiments can be stated briefly because they were uniform when the dosage did not exceed the tolerance for the particular

dog under observation and when the reaction of the dog to the potassium ion in the drug did not produce a rise in the blood pressure and cardiac fibrillation which resulted in death. We were never able to predict which animal would exhibit these reactions. If the animal's tolerance was exceeded with the initial injection, death occurred promptly. That cardiac fibrillation was the reaction of the heart to the potassium ion in the drug, with a resulting sharp rise in the blood pressure, was proved in several animals by the injection of sodium sulfocyanate without such an effect. Occasionally, in some normal dogs the pressor effect of the potassium ion overshadowed the common depressor effect of the cyanates.

Fig. 2.—Blood pressure response and coronary outflow of normal dog (weight, 13 kg.) to intravenous injection of 0.50 Gm. of potassium sulfocyanate. Note sudden increase in coronary outflow, coincident with fall in pressure.

The usual prompt fall in blood pressure following injection of potassium sulfocyanate intravenously in small doses (0.013 Gm. per 1 kg.) makes it difficult to regard the effect as based upon anything other than a vasodilator mechanism (Fig. 1). The increased coronary outflow (Fig. 2) would seem to corroborate this view. Any explanation for the action of the cyanates as a protoplasmic toxic agent would not appear logical in the presence of such a prompt response. Fig. 3A illustrates the beginning of a blood pressure drop following an injection of potassium sulfocyanate which is quickly overtaken by the pressor action of the potassium ion and evidence of a beginning cardiac arrhythmia. Fig. 3B illustrates the more definite depressor response in this same animal to a similar dose of potassium sulfocyanate after the splanchnic nerves

Fig. 3.—Blood pressure responses in normal dog (weight 18.2 kg.) to an intravenous injection of 0.50 Gm. of potassium sulfocyanate (A) before and (B) after supradiaphragmatic splancinctomy.

Fig. 4.—Blood pressure responses in dog with experimental hypertension (weight 20.9 kg.) and a blood cyanate level of 33 mg. to an intravenous injection of 0.50 Gm. of potassium sulfocyanate (*A*) before and (*B*) after supradiaphragmatic splenectomy.

were sectioned. This would seem to point definitely to the effect of the removal of the vasoconstrictor mechanism in the visceral area supplied by the splanchnics. Similar results were obtained upon dogs which had been given cyanates over a period of several days in order to establish a blood cyanate level. It was noted, however, that it required a smaller dose of the drug to produce a similar quantitative response in the blood pressure in these animals.

Fig. 4 (*A* and *B*) illustrates the response of the blood pressure in a hypertensive dog in which a partial ischemia of both kidneys had been produced several months previously by the application of Goldblatt clamps to the renal arteries. This particular animal had been fed potassium sulfo cyanate for several weeks and had been proved to be responsive to the drug, as evidenced by a fall in the mean arterial pressure and significant changes in the blood chemistry. Before this experiment was carried out, cyanate administration had been stopped and the blood pressure had returned to its previous high level. Fig. 4*B* shows the increased response after splanchnicotomy to the same dose of potassium sulfo cyanate as was injected in obtaining the tracing shown in Fig. 4*A*. Again the promptness of the response to injection of the cyanates speaks for a direct vasodilator action as against a general toxic depressor effect.

SUMMARY

From the results of acute experiments carried out upon normal dogs, ischemic hypertensive dogs, and normal dogs with elevated blood cyanate levels, it would seem logical to believe that the effect of the intravenous injection of potassium sulfo cyanate produces its depressor effect as the result of a general vasodilatation. This effect can be increased by removal of the thoracic sympathetic trunk and splanchnic nerves supradiaphragmatically. These experimental observations lend support to the observation made clinically that in many instances patients who respond poorly to cyanate therapy may become sensitive following a bilateral splanchnicotomy.

CLINICAL CHEMISTRY

THE ACID-BASE BALANCE AND WATER CONCENTRATION OF THE BLOOD DURING THE TOXEMIAS OF LATE PREGNANCY*

FRED W. OBERST, PH.D., LEXINGTON, KY., AND E. D. PLASS, M.D.,
IOWA CITY, IOWA

A NUMBER of reports on the acid-base balance in the blood during the toxemias of late pregnancy have appeared recently.¹⁻⁵ Although there is some variation, depending upon the type and severity of the toxemia, it is generally agreed that the acid-base values are within the accepted range for normal pregnant women, except shortly after a convulsive seizure, when the bicarbonate and pH values are abnormally low, and during coma, when there is an acidosis caused by uncompensated alkali deficit (Van Slyke, area 9).

For the purpose of this study, the toxemias of late pregnancy are divided into three clinical groups: (1) chronic cardiovascular renal disease (essential hypertension, arteriolar sclerosis), (2) toxemia without convulsions, and (3) toxemia with convulsions (eclampsia). This classification has been employed in the clinic for some years and has proved to be satisfactorily simple. Patients representing each of these three groups were studied to determine the water concentration of the whole blood and the acid-base balance of the plasma by methods similar to those employed in investigating the blood changes in normal women during late pregnancy.^{6, 7}

METHODS AND MATERIALS

The analytical methods and necessary calculations were those described previously^{6, 7} in studies of normal pregnant women, similar precautions being observed during collection and analysis. Determinations included the water content and specific gravity of plasma and whole blood, the cell volume and hemoglobin content of whole blood, and the concentration of the important acidie and basic constituents of plasma.

RESULTS

Chronic Cardiovascular Renal Disease.—The clinical data on the nine patients in this group are presented in Table I; the blood chemical findings, in Tables I-A and I-B.

Comparison with the average values noted in the blood of normal pregnant women^{6, 7} shows little variation, although the hematocrit reading is somewhat elevated and the water in the cells is below normal. By reason of the depression of the chlorides, the average total acid is in the lower range of normal, as

*From the Department of Obstetrics and Gynecology, State University of Iowa.
Received for publication, February 14, 1940.

is the average total base, because of the diminished sodium content. Both variations may be explained by the lowered concentration of sodium chloride.

Toxemia Without Convulsions.—Data on the fifteen patients in this group are presented in Tables II, II-A, and II-B.

The water content of the plasma is slightly higher than in the hypertensive patients, but the cell water values are similar. The total bases and the total acids are both within the ranges found in normal pregnant women.

Toxemia With Convulsions.—Data on the seven patients with convulsive toxemia are presented in Tables III, III-A, and III-B.

The cell volume, the hemoglobin, the specific gravity of whole blood and plasma, and the water content of the plasma are within the ranges found in normal pregnant women, whereas the water content of the blood cells is significantly reduced.

The average values for total acids are in the lower range for normal pregnant women. Evidently the reduced acidity is caused by a diminution of the bicarbonate rather than by a lowering of the chloride concentration. This change more than compensates for the slight increase in the sulfates.

The average values for total base are slightly lower than in normal pregnant women, a finding which is contradictory to the observations of Stander, Eastman, Harrison, and Cadden.¹ The plasma pH values are generally lower than those for normal pregnant women, especially when the blood is drawn shortly after a convulsion.

DISCUSSION

The results generally confirm observations previously reported and support the contention of Kydd, Oard, and Peters² that changes in the acid-base balance of the blood in women suffering from the toxemias of late pregnancy are probably the result of the disease, and that therapy should logically be directed at the relief of the symptoms rather than at the correction of the slight, and possibly temporary, alkali deficit by the administration of alkalis.

Edema, which is a recognized component of the clinical syndrome of the late pregnancy toxemias, was manifest in the majority of the patients studied, although its extent varied markedly. The amount of edema appears to be unrelated to the water content of the plasma or whole blood, or to the plasma proteinate. This latter observation appears to be contrary to earlier work, which showed that the plasma protein concentration diminishes with increasing edema. Peters, Wakeman, Eisenman, and Lee³ have pointed out that the base-binding capacity of the total protein varies with the albumin-globulin ratio, becoming significantly less as the ratio diminishes. It is well recognized that in edema the diminution of the total plasma protein is largely caused by a reduction in albumin. Such a change would lower the ratio and consequently lead to a proteinate value which is too high. Assuming the correctness of this argument, the findings here recorded are in reasonable accord with previous observations. Moreover, it is obvious that if the recorded proteinate values are too high, the recorded values for total acids both in normal pregnant women and in those with toxemia would also be too high, and that the variations should be more marked in the latter group where the reduction of the A/G ratio is greater.

*A value of 0.8 was assumed for [SO₄]⁻ --

†Determined colorimetrically and corrected to electrometric values by subtracting a determined value of 0.34.

The average values for plasma pH show no marked variation, but there is a significant diminution in those women with convulsive toxemia (eclampsia). Tables III and III-B show that the lowest values were obtained shortly after convulsions. For example, in Case 80, where the blood sample was drawn three minutes after the last (seventh) convulsion, the pH was 7.04, whereas in Case 17 b, a value of 7.22 was obtained several hours after the fifth attack, while the patient was still comatose. In these instances the low pH was associated with

a marked reduction of the bicarbonate. While no determinations for lactic acid were made, it seems probable that these observed changes toward the acid side were due to an accumulation of lactic acid developed in the organism as a result of the convulsive seizures, as emphasized by Stander.^{9, 10}

SUMMARY

The acid-base balance in the blood has been studied in thirty-one women suffering from various forms of the toxemia of late pregnancy (nine hypertensive, fifteen nonconvulsive, and seven eclamptic patients). In general, the findings confirm the work of previous investigators by demonstrating a slight alkali deficit, without any significant change in the hydrogen-ion concentration, except in eclampsia, where a convulsive seizure is followed by a marked reduction in the bicarbonate and an associated, proportional lowering of the pH.

On the basis of accumulated evidence, it would appear that the altered acid-base relationships of the blood in patients with pregnancy toxemia are of minor importance, and that any serious metabolic disturbances accompanying this disease entity must be sought in some tissue other than the blood.

EFFECT OF DIET ON ARTERIAL AND VENOUS GLUCOSE TOLERANCE CURVES IN RHEUMATOID ARTHRITIS*

K. R. ANDREWS, M.D., AND R. O. MUETHER, M.D.
ST. LOUIS, MO.

CHRONIC rheumatism is the center of considerable investigative work since it is one of the chief diseases causing partial or total disability in man. Rheumatoid arthritis is a type of chronic arthritis which is especially important economically since it attacks the young adult, as a rule, and converts an economic asset into a liability.¹⁻⁴ Considerable investigative work has been done in an effort to explain the causes, as well as changes, that occur in the body of the patient afflicted with this disease. The possibility of some derangement in the metabolic or endocrine system of the body has been considered as a possible etiologic factor;⁵⁻⁸ however, chronic infection seems to interest the greatest number of investigators.¹¹⁻¹³

Regardless of etiology, certain alterations in body economy are said to exist in the rheumatoid types of arthritis; there is a loss of muscle bulk, diminished circulation, and gastrointestinal stasis. Certain alterations in the chemistry of the body are also said to occur. A diminution in the blood content of vitamins B and C has been reported,^{9, 10} and there is said to be a diminished tolerance for glucose.¹⁴

Pemberton and others have shown that the arthritic person does not remove glucose from the blood as promptly as the normal individual. Because of the apparent reduction in carbohydrate metabolism, many investigators recommend low carbohydrate diets for the rheumatoid arthritic patient and have reported marked relief from pain when patients are placed on a high fat, low carbohydrate diet.

The experience of our clinic has been similar to that of Pemberton and others, in that the majority of the patients studied had a decreased tolerance for dextrose. We have felt that this diminished tolerance might also be explained by an impairment in the glycogenic function of the liver. If this is the case, improvement in the carbohydrate metabolism would be expected with a high carbohydrate rather than a high fat diet. Since glucose tolerance tests done on venous blood give only an idea of the blood sugar after the blood has coursed through the muscles, it was thought that a better idea regarding the ability of the liver to remove glucose from the blood would be obtained by the simultaneous estimation of both arterial and venous blood. In this way the level of the blood sugar could be ascertained after the blood has passed through the

*From the Laboratory Division, Department of Internal Medicine, St. Louis University Group of Hospitals.
Received for publication, November 30, 1939.

liver but not through the muscles. If the arterial blood sugar is high, the ability of the liver to remove sugar from the blood is impaired. On the other hand, if both the venous and arterial blood sugars are high and tend to approximate each other, the glycogenic function of both liver and muscle is impaired, since, when muscle function is good, the arteriovenous difference should be marked. It has been reported by Sweeney, and confirmed by others,¹⁶ that a high carbohydrate diet improves carbohydrate utilization in normal individuals. It was felt that it would be of value to determine whether: (1) diet had the same effect on the glucose tolerance of arthritic patients as that of normal individuals; (2) improvement followed one of the two diets used, whether it was due to improved liver or muscle function; (3) what the effect of the respective diets on the well-being of the patient might be.

PROCEDURE

Patients with typical rheumatoid arthritis were selected for the study with each patient showing varying degrees of muscle wasting and joint involvement of from two to twelve years' duration. Each patient was carefully examined for foci of infection. Blood nonprotein nitrogen, sugar, cholesterol, uric acid, Wassermann, and gonococcal complement fixation determinations were studied. Complete blood counts were done and chest x-ray studies were made.

Eleven patients, eight males and three females, were found to be suitable for this study; all had normal values for the above determinations. Each patient remained afebrile during the study and only occasionally received codeine with salicylates as symptomatic treatment. Three normal subjects, two females and one male, were also selected for the same study and acted as controls. Those selected were hospitalized and placed first on a high fat, low carbohydrate diet for two weeks; then on a high carbohydrate, low fat diet for another period of two weeks. At the end of this period the patient remained on a high carbohydrate diet but was given 10 units of insulin before each meal for a third period of two weeks. At the end of each period complete arteriovenous glucose tolerance tests were run on each patient, the arterial and venous bloods being collected at the same time. The various diets were equicaloric and contained an equal amount of protein. The high carbohydrate diet contained from 350 to 450 Gm. of carbohydrate and from 40 to 50 Gm. of fat, while the high fat diet contained from 200 to 225 Gm. of fat, and from 70 to 80 Gm. of carbohydrates.

The glucose tolerance test was run over a three-hour period. Following the collection of the fasting specimen of blood, a solution containing 100 Gm. of dextrose was taken by mouth. Specimens of blood were obtained from the cubital vein after thirty minutes, sixty minutes, two hours, and three hours. The arterial blood was collected from the finger tip simultaneously with the venous puncture, since it has been shown that cutaneous and arterial blood are identical in sugar values.¹⁷

RESULTS

Table I represents the results obtained in the three normal individuals. It will be noted that a lowering in the blood sugar curves occurred following a high carbohydrate diet. The glucose tolerance curve was more elevated after

the patient had been given insulin, plus a high carbohydrate diet, than it was when the patient was on a high carbohydrate diet, but the elevation was less than when the high fat diet was taken.

In the patients listed in Table II only venous sugars were obtained. It will be noted that the venous levels following a high fat diet reached almost diabetic proportions; however, following a high carbohydrate diet, the curves were considerably flattened.

TABLE I

PATIENT	DIET	MG. % SUGAR	TIME—MINUTES					AVG. DIFF. AT 30 MIN. (MG. %)
			FASTING	30	60	120	180
